**CETONIIDÆ** (MacLeay). A family of coleopterous insects, belonging to the section *Pentamera*, and to the sub-section *Lamellicornes*, forming a portion of the great Linnæan genus *Scarabæus*, and corresponding with the section *Melitophila* of the Règne Animal. The body is depressed, generally oval, and gaily coloured; the head and thorax seldom cornuted; the thorax ovate-quadrate, or suborbi-

the latter, the structure indicates strong biting and lacerating powers; but in the *Cetonia*, the formation will serve only for lapping up vegetable juices, and we accordingly find that some of the species prefer the sap which flows from the wounds of trees, whilst others sip, with evident delight, the nectar of flowers.

These insects are distinguished from the family of cock-chafers (*Melolonthidæ*), by the maxillæ not being terminated by several robust teeth as in the latter, by the upper lip being concealed by the clypeus, and by the antennæ, which are terminated only by a three-jointed fan.

The green rose-chaffer (*Cetonia aurata*) is one of the commonest, as well as one of the most beautiful, of our British beetles. It is found, very abundantly, during the summer months, especially in gardens, and frequenting the flowers of the rose, elder, peony, &c. We have also noticed that it is extremely partial to the privet, having observed a hedge of that tree, in the neighbourhood of Fulham, completely swarming with them. They fly well, with a considerable humming noise, during the hottest part of the day. This species is of a fine golden green colour, very shining above, and of a bright copper colour beneath; the wing covers are ornamented, near the tips, with numerous transverse narrow white markings. According to Latreille, these insects do not attack the essential parts of flowers, contenting themselves with merely sucking the honey from the bottom of the corolla. However, this may be, it appears that another species of the genus, (the *Cetonia hirta*), is very injurious to the flowers of the apricot in Malta—an account of its ravages having been published by M. St. John, in the Magazine of Natural History, No. XXIII. Of this insect, which the Maltese call Bouzuff, and the English inhabitants the Botany Bay, this author observes, "After he has filled himself, he retires under ground till the March apricot blossoms, when he emerges, and I am, for two months, obliged to have people employed solely to pick him off the blossoms, of which he readily eats the nectary, and having eaten one he goes to the next; he is very active, and flies like a bee. When the roses are in blossom, these beasts are so fond of them, that you may take twenty out of one flower, and in ten minutes as many more—a dark-coloured flower they never touch." Upon the commencement of this passage we would, however, observe, that it would therefrom be naturally inferred, that the writer supposed either that the animal maintained the same form on emerging in March, as it possessed on retiring under ground, or, at least, that the grub of the cetonia

The Rose-chaffer in its different shapes.

cular; a corneous plate (forming portion of the sides of the meso-thorax, greatly developed,) occupies the space between the posterior and lateral margins of the thorax, and the external base of the elytra. The elytra are generally shorter than the body, the extremity of which is consequently exposed; the sternum is often prolonged into a point, thus resembling the *Buprestidæ*; the scutellum is generally distinct, and the tarsi are provided with equal sized simple claws; the antennæ are ten jointed, the club being composed of three joints. The structure of the mouth, which affords so complete an idea of the nature of the food of insects, is here remarkable. The upper lip and jaws, instead of being horny, as in the majority of beetles, are reduced to thin membranous plates, incapable of gnawing; the maxillæ are also terminated by a very hairy lobe, in the shape of a pencil, without horny teeth, and are only furnished with a single palpus. Now, on comparing this description with the figure of the under jaw of a predacious beetle, given in our article *CARABIDÆ*, the difference will be perceived to be very striking. In

had filled itself (it is not stated with what) in an exposed manner above ground, then retired into the earth, from whence it emerged in the perfect state in March. Neither of these ideas would, however, be correct, because the perfect cetonina only appears above ground for a short time in spring and summer, retiring thither again for the purpose alone of depositing her eggs, which is the last act of her existence. Moreover, the grubs of the cetonina do not feed above ground, but in rotten timber and wood; and, indeed, it is remarkable that the larva and pupa of the common rose-chaffer are often found under ground in ants' nests, where, it would seem, they support themselves by feeding upon the bits of wood of which the nests are composed, and without being attacked by their hostile hosts. From this circumstance they are called, in some countries, the king of the ants. After remaining two or three years in the larva state, they may be considered as full grown, when the larva makes a cocoon of bits of sticks, guten, &c., in which it becomes an inactive pupa, and from which, in the following summer, it emerges.

Some difference of opinion exists as to the food of the larva of these insects; some authors supposing that they feed upon the earth in which they live, whilst others state that they attack the roots of living plants; and by some it is affirmed, that in this state they scarcely do any mischief to plants, feeding upon putrescent wood.

This family, which corresponds with Latreille's section *Melitophilæ*, is divisible into three sections. First, the *Trichides*, having the sternum not produced into a point, the thoracic lateral scales not developed, and the lower jaws not concealed by the chin. Here belong the British genera *Trichius*, *Gnorimus*, and *Valgus*, and some others proposed by Mr. Kirby in the Zoological Journal, and by Messrs. Gory and Percheron in their very beautiful *Monographie des Cétoines*, now in course of publication. In this first section we possess but four British species, which have been until recently placed in the genus *Trichius*, but the diversity of their habits sufficiently warrants their separation. Thus the beautiful *Trichius fasciatus* is always found upon flowers, whilst the *Gnorimus variabilis* not only passes its larva state within the bodies of decayed oak trees, but is found, on arriving at the perfect state, on the trunks of such trees. The *Valgus hemipterus*, on the contrary, is commonly found on the ground, where it creeps but slowly. This, and some North American species, are distinguished by the horny spear-shaped ovipositor at the extremity of the body, which evidently is employed by them to bore a hole in the earth for the reception of their eggs.

The second section, *Goliathides*, is distinguished from the preceding by the large size of the mentum which conceals the lower jaws. Here belong various exotic genera, of whose habits nothing is known, including, however, some of the largest and most beautiful species of lamellicorn insects.

The third section, *Cetonides*, have the sternum pointed, and the lateral thoracic plates developed. Here belongs the British genus *Cetonia* (containing two British species) and various other exotic genera.

**CEYLONITE.** A mineral which derives its name from Ceylon, to which island it was originally supposed to be exclusively confined. It is now, however, found in considerable quantities in the rocky beds of the Rhine, and in several volcanic

districts. This mineral is distinguished from SPINEL, which see, by its semi-metallic lustre, inferior hardness, greater specific gravity, and inferior transparency. When it occurs in grains, it is apt to be confounded with tourmaline; but its semi-metallic lustre, greater specific gravity, and its not becoming electric by heating, distinguish it from that mineral.

**CHÆROPOTAMUS.** A name given by Cuvier to a genus of fossil pachydermata found in the gypsum in the neighbourhood of Paris, where it accompanies the remains of the anoplotheria and palæotheria, but is of much rarer occurrence than either of these. But little of this animal has been found, excepting the teeth and some parts of the head. The incisors (if there were any) have not hitherto been discovered. The canine tooth in the lower jaw is pointed, and tolerably large, and an empty space occurs between it and the first molar-tooth, which is conical, pointed, and slightly compressed, but by no means trenchant; it has two thick roots, which separate as they enter the alveolus. The second molar is rather more compressed, having also two roots; and behind its points, which are blunt, are two other points much lower, and scarcely projecting, which form a second lobe. Two teeth follow, which are tuberculated, having four principal tubercles on the coronal, which is nearly rectangular; two smaller tubercles occur in the middle of the others, and there are some other inequalities about their bases. These teeth resemble very closely the third and fourth molar teeth of the babyroussa, and, generally speaking, teeth of this description indicate an animal of the swine family; but no known animal of this kind has the first molar of this conical form, and the peccary alone has a canine tooth as small as the chæropotamus, and besides is a much smaller animal than this appears to have been.

From these and other fragments, Cuvier was led to the conclusion, that the plaster quarries contain the remains of an animal approximating more nearly to the genus *Porcus*, than either the anoplotherium, or the palæotherium, which however differed in many particulars from any species of swine now existing. He offers as a conjecture, that the dichobunes, whose feet so nearly resemble those of swine, approached very nearly to this new genus, and possibly formed the link between it and the anoplotheria, properly so called. But one species (the *Parisiensis*) has hitherto been noticed.

**CHÆTODON**—bristle-tooth. A genus of spinous finned fishes, belonging to Cuvier's sixth family of the division, or those with scales on the fins. They obtain their name from the very peculiar form of the teeth, which are long, slender, and bristle shaped, ranged in several rows, and bearing some resemblance to brushes. Their mouth is very small; their dorsal and anal fins are covered with scales, not easily distinguishable from those on the back. They are exceedingly numerous in the warm seas, and many of them are so gay in their colours, that they are sought after with some avidity by collectors, as cabinet fish. Their intestines are long and large, with numerous long but slender cæca. The air-bladder is very large. They are usually found near reefs and rocky shores; La Cépède has enumerated forty-two species. Their flesh is excellent food, and they are much sought after by the sailors. They are remarkable for their form, and the brilliancy and variety of their colours. The limits by which the different species are separated are ill

defined, so that much confusion prevails in their nomenclature. They all inhabit the seas of tropical countries, and were unknown or disregarded by the ancients. The skeletons of some species have been found, along with other ruins of the animal kingdom, in the strata at Mount Bolca. La Cépède particularly mentions the remains of the *C. vespertilio* and *terra*. The *C. marginatus* appears to prefer the mouths of rivers, is very common at the Antilles, and its flesh is good. The flesh of the *C. macrolepidotus*, a native of the East Indies, is said, in point of delicacy, to resemble the sole. But the most extraordinary species is the *C. rostratus*, a native of the fresh waters of India. Dr. Shaw, after informing us that its prey consists of the smaller kinds of insects, says, "When it observes one of these, either hovering over the water or seated on some aquatic plant, it shoots against it from its tuberos snout a drop of water, with so sure an aim, as generally to lay it dead, or at least stupified, on the surface. In shooting at a sitting insect, it is commonly observed to approach within the distance of from six to four inches, before it explodes the water. When kept in a state of confinement in a large vessel of water, it is said to afford high entertainment by its dexterity in this exercise; since, if a fly or other insect be fastened to the edge of the vessel, the fish immediately perceives it, and continues to shoot at it with such admirable skill, as very rarely to miss the mark."

In whatever part of the world they are found, these fishes are equally remarkable for their singular forms, their brilliant colours, and their great activity. They are so remarkable in these respects, that they have sometimes been described as occupying a similar place in the tropical seas to that which the parrots occupy in the tropical forests; and though, as is the case with all fishes, their colours fade much more after death than those of birds; they perhaps excel the parrots in brilliancy while they are alive. All their colours have a metallic lustre, and though some of them are of one very intense colour, as for instance golden yellow, ultra-marine blue, or rich bronze, when the fish is at rest, yet, when it moves, they are all iridescent and sparkle with a gem-like lustre. They are also exceedingly numerous, both in species and individuals, and as they keep near the surface, and frequently spring into the air, they have a very brilliant effect. The variety of them is, indeed, so great, that they have hitherto set description at defiance; and a mere list of them would occupy too much space in a work of this kind. Cuvier divides them into several sub-genera, of which, and one or two of the leading species, we shall give very short notices.

I. CHÆTODONS properly called. These have the body more or less elliptic, the spinous and soft rays of the fins are continued in a curve which is not very uniform; the muzzle is differently produced in different species; and in some of them the gill-flap is armed with a small tooth. The spines of the dorsal are sometimes very much produced. Most of the species of this sub-genus inhabit the eastern tropical seas. The following are some of the principal genera:—

*Chatodon striatus*, this species is sometimes called the zebra, on account of its stripes. It has the head and gill-cover armed with the same scales as the back; two openings to each nostril, the vent much nearer the head than the tail, the caudal fin is rounded. Its general colours are:—the ground a beautiful yellow, with four or five transverse bands of brown on the sides, and the pectoral fins black. It is one of the

largest species, and also plentiful; and its flesh, which is white, firm, and well flavoured, is much sought after.

*Chatodon unimaculatus*. This species is sometimes called the black spot; its distinguishing characters are, the tail forked, a black band crossing the nape, including the eyes, and extending down to the gill-covers, and a single large spot on each side of the back. It is found principally in the North Pacific, toward the Japan and Philippinean islands.

*Chatodon capistratus*. This species has the tail rounded, the black band on the head straighter, and the black spots on the back surrounded with white. It is found in the same seas with the former species.

Those which we have mentioned are but a very few of the species or varieties of this abundant and interesting sub-genus; but the differences, though conspicuous enough, are not very important, as they are almost wholly differences of colour only.

II. CHELMONS. This sub-genus has been separated by Cuvier from the chatodons properly so called, in consequence of the peculiar form of the muzzle, which is slender, very much elongated, and has some resemblance to a whistle. The known species are inhabitants close in shore, and are understood to subsist chiefly upon air insects.

*Chatodon rostratus*. This is a very beautiful species, the ground colour being golden and silvery in alternate bands, with an ocellated spot, black in the middle and surrounded with white, immediately in the rear of the dorsal fin; this is the species formerly alluded to as being dexterous in shooting flies. In consequence of the beauty of its colours, and the liveliness of its action, it is often kept in vases by the people of the east, in the same manner as gold fishes are kept in this country.

Another species with the muzzle still more elongated, and of a lemon yellow colour with some black spots, has been described as inhabiting the South Sea.

III. HENIOCHUS—Coachmen. This sub-genus get their common name from one long filament proceeding from the dorsal fin, and sometimes extending to twice the length of the body. The form of this filament is not unlike that of the cord of a coachman's whip. The following is one of the principal species:—

*Chatodon macrolepidotus*. This is a large species, being sometimes met with of the weight of twenty-five pounds. Its flesh is very much esteemed; and its colours are brilliant, being very splendid, silvery in the greater part of the body, and crossed by two brown bands on each side. Several other species of this sub-genus are mentioned by systematic writers, but the accounts of them are not a little confused.

IV. EPHIPPUS—Horsemen. The principal character of these is a deep notch between the spinous and soft parts of the dorsal fin. The spinous part is without scales. This division is found both on the American coast and the east, and the species are very numerous.

V. HOLOCANTHUS. The leading character of these is a large spine on the angle of the gill-flap, the edge of which is also toothed. Like the preceding sub-genus, they are found both in the Atlantic and Pacific. The species is very numerous, their colours are beautifully arranged, and they are much esteemed as food.

VI. POMACANTHUS. These have the body more elevated, and their dorsal fin rises higher than in most of the species. They have been met with only on the American shores.

VII. PLATAX. These have their teeth closely set, the first row being trenchant, and each consisting of three points. Their bodies are very much compressed

or flattened sideways (hence their name). Their fins are very much elevated and covered with scales, so like the rest of the body, that they seem a continuation of it. There are a few small spines on the anterior edge of the dorsal, and the ventral fins are very long. The height of the fish, seen sideways, exceeds the length. There are several species of them, all natives of the Indian seas; and they are called sea-bats, and other fanciful names by the sailors. Some of them are found in the Red Sea.

**CHAFFER.** The common English name whereby various species of beetles are called, evidently adopted from the German *Käfer*, which is, however, employed as synonymous with the whole of the coleopterous insects to which we have applied the name of beetle. In Germany, however, from the great richness of the language, a distinct name is applied to every species of coleoptera; but in England, owing to the poverty of our tongue, and the small degree of attention hitherto paid to the subject, but very few insects have obtained vernacular names; and amongst these we find the term chaffer almost exclusively applied to beetles belonging to the Linnæan genus *Scarabæus*. Thus the *Melolontha vulgaris* (*Scarabæus vulgaris* of Linnaeus) is commonly called the cock-chaffer, whilst the *Cetonia aurata* (*Scarabæus auratus*, Linnaeus) has received the name of the rose-chaffer, &c. Of these, the first-named insect is by far the most obnoxious, from its destructive powers, whilst in the larva state, to grass, &c., devouring the roots. As, however, the name chaffer is not exclusively applied to this insect, it will be more convenient to defer its account until we arrive at its systematic place, under the article *MELONTHIDÆ*. See also *COLEOPTERA*.

**CHAILLETIACEÆ.** A natural order of dicotyledonous plants, allied to *Terebinthaceæ*, *Rosaceæ*, and *Aquilarineæ*, containing three genera, and seven known species. Its essential botanical characters are: calyx persistent, five-cleft, coloured within, with an imbricated aestivation; petals five, alternate with the segments of the calyx, and arising from the bottom of it; stamens five, alternate with the petals; anthers roundish; ovary free, hairy, from two to three-celled; styles two or three, short, free or coalescing; fruit dry, two or three-celled drupes; seeds solitary, without albumen; embryo thick, with a short, superior radicle, and fleshy cotyledons.

The plants belonging to this order are trees or shrubs, with alternate, stipulate, ovate leaves, and axillary white flowers. They are natives of tropical regions, and are found in South America, and in the islands of Madagascar and Timor. The genera of the order are *Chailletia*, *Leucosia*, and *Tapura*.

*Chailletia Toxicaria*, or rat-bane, is a branching shrub, from six to twelve feet high, which grows on the mountains near Sierra Leone. It bears small white flowers, and yields a fruit the size of a pigeon's egg, which possesses poisonous properties. The kernel is used by the negroes for poisoning rats and mice. In other respects the properties of the order are not known.

**CHALCEDONY.** A mineral much in request in ancient times, and which appears to have derived its name from Chalcedon, a miner who first discovered it. Its basis is usually of a semi-opaque character; and if we may judge from the descriptions given by Pliny and some other of the early authors, it would rather appear that the gems they describe under this name were of a more beautiful character

than those we now employ. There are four well-known forms of the chalcedony; the first resembling a common flint, and is usually found in masses of two or three inches in diameter. Under this head we may place the oriental chalcedonies, which are the only ones of any value. They are found in vast numbers on the banks of the rivers in all parts of the East Indies. The second form is of a milky colour, and is of little value. It is principally found in South America. The third form is exceedingly dark and cloudy, and was known to the ancients by the name of smoky jasper. It is at the present time much used in Germany, and worked into the handles of knives. The fourth kind is usually of a yellow or red colour. It comes from the East Indies, and the Italians employ great quantities in the manufacture of their rosaries.

The dendritic chalcedonies, or mocko gems, are much prized as ornamental stones. The arborisations are black, red, brown, or green. The black are the most common, and most distinct; the red, on the contrary, are rarer, and are less distinct, and are named *corallines*, from the resemblance of the dendritic delineations to coral; and the green are rare, and much esteemed. These arborisations appear in some cases to be owing to iron, in others to manganese and iron. Dutens, Von Moll, Daubenton, Blumenbach, and Dr. Macculloch, maintain that many of them are of a true vegetable nature. Dutens says, that if the plants contained in chalcedony are extracted, and the fragments thrown on burning charcoal, a bituminous smell is exhaled; and Von Moll maintains, that chalcedony sometimes contains brown and green moss.

Lenz affirms, that the chalcedony found in the amygdaloid of Deuxponts, contains musci of different kinds, such as lichen rangiferinus, confervæ, and byssi. And Blumenbach says, in a letter to Baron Von Moll, that though he had hitherto disbelieved the occurrence of vegetable bodies in the dendritic variety of chalcedony, named mocko-stone, yet he must now admit that it does sometimes contain plants, apparently of the nature of conferva. He observed these in specimens from Iceland and Catherinenburg. The same celebrated naturalist maintains, that he found, in the interior of an agate, the fructification of an unknown plant, somewhat resembling the *Sparganium erectum*.

**CHALCIDIDÆ.** A family of very minute hymenopterous insects, belonging to the section *Pupinora* of Latreille, and forming Linnaeus's section *Ichneumonones minuti*. This family is distinguished by the wings being almost entirely destitute of nervures, and the antennæ, which are strongly elbowed at the extremity of the long basal joint, are short, and composed of not more than thirteen joints. These minute creatures are amongst the most effective agents to be found amongst the insect tribes employed in the parasitic destruction of their larger brethren, the females being unceasingly employed in searching for and depositing their eggs in the bodies of other insects, almost every order being alike subject to their attacks. It is, however, to the destruction of the larvæ of lepidopterous insects that their labours are for the most part devoted. A very common instance of their proceedings may be observed in the chrysalis of the nettle-tortoiseshell butterfly (*Vanessa urticae*), which is often to be seen, as it were, bored through with numerous small holes, whence, instead of the

perfect butterfly, an infinity of minute and beautiful little creatures have escaped. This circumstance seems not a little to have perplexed the old naturalists. How a creature, which ordinarily produced a beautiful butterfly, should, at certain times, produce myriads of other smaller insects, was one of those hidden secrets of the creation which they knew not how to fathom; and we find even the great Swammerdam mentioning it as "a thing very wonderful, that 545 flies of the same species were produced from the chrysalides of four butterflies, so that the life and motion of these four creatures seems to have transmigrated into those of the 545 others;" and even the philosophical Ray at first thought that it arose from some defect or weakness in the caterpillar which would prevent the perfect development of the butterfly; and therefore, in order that the maxim, "*Natura nihil frustra fecit*," should not be defeated, she stopped short, and formed them into more imperfect animals. And in the argument which he subsequently used in his admirable work, "*The Wisdom of God in the Creation*," against the doctrine of equivocal generation, we find the same learned author thus expressing himself:—"You will say, How comes this to pass? Must we not here necessarily have recourse to a spontaneous generation? I answer, No. The most that can be inferred from hence is a *transmutation of species*. One insect may, instead of generating another of its own kind, beget one of a different. *But I can by no means grant this*. I do believe that these flies do either cast their eggs upon the very bodies of the fore-mentioned caterpillars, or upon the leaves, upon which they feed, all in a string, while those hatching eat their way into the body, where they are nourished till they are come to their full growth. Or it may be, the fly may, with the hollow and sharp tube of her womb, punch and perforate the very skin of the ercua, and cast her eggs into its body. The discovery of the manner of the generation of these sorts of insects I earnestly recommend to all ingenious naturalists as a matter of great moment. For, if this point be but cleared, and it be demonstrated that all creatures are generated unequivocally of parents of their own kind, and that there is no such thing as spontaneous generation in the world, one main prop and support of Atheism is taken away, and their strongest hold demolished, they cannot then exemplify their foolish hypothesis of the generation of man and other animals at first, by the like of frogs and insects at this present day." In what a striking point of view do the arguments of this good man appear, now that it is known that the suppositions upon which some of them were founded so completely correspond with what takes place in nature; the only part of them not being found to be strictly correct being the idea, that these parasites laid their eggs on leaves which might be frequented by the caterpillars, an idea evidently derived from the general and incorrect principles to which the presence of blight is usually attributed, and to which we have already alluded in our article upon that subject.

These little animals, of which we probably possess 1500 British species, are highly beautiful in their form, and their colours vie with those of the humming birds. We find gold and purple, copper and green, intermingled in the most elegant order, thus forming exquisite microscopic objects, whilst many of them are highly singular in their appearance. In fact, they appear to be the counterparts of the cercopides

amongst the homoptera, possessing, like them, the power of leaping to a very great distance, although their legs are very seldom incrassated. This, however, is the case in the typical genus *Chalcis*, of which we possess several British species, but which, singularly enough, do not possess saltatorial powers, although their posterior femora are very large. The genera, of which the investigation has been greatly neglected until recently, are very numerous.

CHALK. This universally diffused substance is too well known to need any particular description of its external characteristics. We have manifest proofs, in our own country, that this deposit must have experienced very considerable changes in its geological arrangement by the action of water; for the vast beds of gravel which are still employed in the formation of roads, &c., have evidently been rounded by attrition, after their separation from the chalk by which they were originally surrounded. In England, chalk extends with little interruption from the coast of Yorkshire to that of Devonshire, while a series of hills extends from Wiltshire to the coast of Kent; and a branch from the centre of the latter ranges to the Sussex coast near Brighton. The Isle of Wight basin comprehends the district between Newport and that island on the north, Brighton on the east, and Dorchester on the west. In Europe, the chalk extends through France and Poland into Russia, and thence to the south of Sweden, is said to occur near the mouth of the Elbe, thence to Flamborough Head in Yorkshire, and thus completing a circuit which may be termed the chalk basin of Europe.

Chalk forms, by its extent and distinctive characters, one of the most remarkable mineral features of England. It would seem as if a considerable interval of time had elapsed between the completion of the original chalk beds and the deposit of others upon it; for the surface of the chalk at its boundary with the superincumbent layers, bears marks of having undergone, during that period, a partial destruction after it was consolidated. There is spread over it a stratum of debris, consisting chiefly of flints washed out of its mass. Moreover, the surface is irregularly worn into numerous cavities, of which many are deep and filled up with the same debris. At the junction of the chalk with the sand and gravel of the plastic clay formation, deep indentations are observed on its surface, which are sections of long furrows and cavities, apparently produced by the action of agitated water before it was protected by the covering of clay. The enormous quantity of chalk flint pebbles, completely rolled and rounded, which are found in the plastic clay to the south of London, show that the chalk itself must have been consolidated before that partial wasting of its upper strata by water. To this hydraulic action, Cuvier and Brongniart ascribe the irregular furrows and ridges on the surface of the French chalk, and the *Muedon breccia*. The immense scale on which this destruction was carried forward may be inferred from the vast extent of the English pebble beds. That a long period of time probably intervened between the deposition of the chalk and of its clay coating is rendered probable also by the total difference of the organic remains found in the two strata.

The band of chalk which stretches across the eastern and southern counties of England, from Yorkshire to Dorsetshire, is to be regarded merely as the western edge of a most extensive tract of this formation. Stretching from the Thames to the Don, the chalk

occupies the interior area of the great central basin of Europe. This concavity is bounded on the north by the primitive mountain districts of Russian Finland, Sweden, Norway, and Scotland; on the west by the transition and primitive chains of Cumberland, Wales, Devonshire, and Britany; on the south by the primitive mountains branching from the Cevennes in the centre of France, the Alps, with the various grand groups of Germany, as the Black Forest, the Rhingau and the Vosges, the Bohemian, Thuringian, Saxon, Silesian, and Carpathian mountains; on the east by the Ural chain and its branches. The chalk does not rest on the mountains themselves, but within the area which they circumscribe at a certain distance from them, an interior area may be traced, over which the substratum of chalk is believed to extend.

Cuvier and Brongniart represent the chalk deposit as forming a sterile soil, and adduce Champagne as a proof of its being in some cases uninhabitable. In our own country the population of the chalk district is certainly less dense than that of many other parts, but it is usually habitable, and to a certain extent productive. Indeed we may say that the chalk valleys are often in this country extremely fertile, of which the Kent and Surrey hop grounds, and the downs for pasturing sheep, afford examples. Beech is the tree best fitted for a chalky soil. The Chiltern Hills, in Oxfordshire, were anciently covered with woods and thickets of beech, which afforded harbour to banditti. The lower beds of the chalk formation are, with few exceptions, filled with water, which percolating from above is arrested by the subsoil of blue clay. Thus are formed the springs and rivulets which issue near the foot of almost every chalk hill.

It is remarkable that America, both South and North, seems to be destitute of chalk. Mr. Maclure asserting positively that it does not exist on that continent. Chalk is well known to have an earthy dull fracture, but it occasionally concretes into a hard limestone. This compact chalk has been used in building. As this formation is composed throughout of a series of homogeneous beds of a tender earthy limestone, it does not admit of stratiform subdivisions.

But the numerous beds of nodular flints, which lie alternately distributed through the greater part of its mass, form one of its most curious and essential features. They are constantly present in all the upper portions of the formation, but are frequently absent in the lower; affording a criterion by which the two may be distinguished. Hence the meaning of the terms *upper* and *lower* chalk.

The uses of this mineral are various. The more compact kinds are employed as building-stones, when they are used either in a rough state, or are sawn into blocks of the requisite size and shape; it is burnt into quicklime, and used for mortar in different countries; it is also employed in great quantities in the polishing of glass and metals, and whitening the roofs of rooms in the state of whitening; in constructing moulds to cast metal in; by carpenters and other artisans to mark with. When perfectly purified, and mixed with vegetable colours, it forms a kind of pastel colour: thus, with litmus, turmeric, saffron, and sap-green, it forms durable colours. The *Vienna white* known to artists is perfectly purified chalk. It is also used by starch-makers and chemists to dry precipitates on, for which it is peculiarly qualified, on account of the remarkable facility with which it absorbs water.

**CHAMA.** Lamarck, in constituting this genus, has separated from the Linnæan arrangement all such shells as have only a thick oblique transverse tooth, resembling a lengthened callosity, in general crenulated or grooved, fitting into a corresponding cavity in the lower valve. The shell is inequivalve, irregular, heavy, rough, scaly, or spinous, having the faculty of affixing itself to other bodies, or to each other in groups, by means of its lower valves. The apices are unequal and recurved; valves with two distinct distant lateral muscular impressions; ligament external and inserted. The characters of these shells, in some respects, ally them to the genus *Diceras*, and in others to the genus *Etheria*. They are, most of them, elegant shells, some with delicate waved or foliaceous valves, some with spines, and pleasingly coloured with yellow, pink, and brown. The animal possesses a suborbicular body, terminated on the upper side with a sort of hook-mantle slightly opened, the foot terminated at its extremity by a portion much narrower than the base; the superior lobes of the branchia very short. The following subdivision of this genus, though not exactly in unison with those of Lamarck, appear to us natural and well defined:—1st, The species that are irregular, inequivalve, without lunule, adhering by the left and largest valve, the two summits turning more or less in a spiral form, the left summit more prolonged than the right, as in the *Chama Lazarus*, and in the same division, those whose summits are prolonged nearly equally, as in the *C. gryphoides*. 2nd, The species subequivalve, subregular, with a distinct lunula, the summits but slightly spiral, adhering by either valve, as in the *C. arcinella*. 3rd, The species which are subregular, half-heart shaped, very inequivalved, the right valve much excavated, the left valve operculated, one conical cardinal tooth, smooth on one side, and fitting into a deep groove on the other valve; ligament as if double, the internal portion much thicker than the external, the muscular impression anterior and very long, as in the *Chama hemicardium*.

This genus is extremely difficult to characterise by any system of teeth or hinge, for each species presents a particular modification, nevertheless, the last division named is so peculiarly different from the others, that without any reference to the animal, it might well form a distinct genus.

These shells are found in all the seas but those of the north; in the southern seas they are more numerous than elsewhere. Eight or ten species are known in a fossil state. They are classed in the third class, *Acephalophora*; third order, *Lamellibranchiata*; seventh family, *Camacea*.

**CHAMÆROPS** (Linnæus). A genus of palms, commonly called the fan-palm. Linnæan class and order *Polygamia Diœcia*; natural order *Palmæ*. Generic character: flowers polygamous; spatha double, leathery, interior side bursting obliquely; florest sitting and bractiate; calyx three-cleft; corolla of three petals; filaments dilated at the base, and connected; stigma three, awl-shaped; berries three, one-seeded. This palm thrives best in sandy loam, and requires moist heat. It is found in the south of Europe, and all warm countries.

**CHAMORCHIS** (Richard). A single plant forming a new genus, formerly called *Ophrys Alpina* by Linnæus. Like other orchises it has tuberous roots, which are liable to be lost if not planted in turf, and kept in a station like their natural one.

**CHAMPACA.** The specific, as well as the Malayan name of the *Michelia*, found at Malacca and other places in that part of India. It is a lofty timber tree, and highly ornamental from its numerous yellow flowers, with which the spray is covered in autumn. It belongs to *Magnoliaceæ*.

**CHARACEÆ—Chara family.** A natural order of acotyledonous or cellular plants, containing one or two genera, and upwards of twenty species. They are aquatic, leafless, submersed plants, consisting of a central axis, from which proceed numerous whorled branches. The axis is composed of parallel tubes, which are either transparent and flexible, or encrusted with calcareous matter, so as to become opaque and fragile. The branches, or leaves, as they used to be called, are smaller tubes of a similar nature. The organs of reproduction in this family of plants are very obscure, but, according to the most recent observations, they appear to be of two kinds.

1. Globules, of a reddish or orange colour, the coats of which are composed of triangular scales, which are at first nicely fitted to each other, and afterwards separate, when the plant reaches maturity. On the margin these scales consist of numerous parallel, colourless, hollow tubes, containing minute orange-coloured bodies, analogous to the sporules of other cryptogamic plants, which are easily dispersed whenever the globules are in any way injured. It is to these little bodies that the globules owe their colour.

2. Minute, sessile, spirally striated, ovate nucules, which are enveloped in a membrane, have frequently five projecting points at the apex, and are filled with minute granular bodies at first distinct, but afterwards coalescing, and giving rise, when they germinate, only to a single plant.

These two sets of organs, the globules and nucules, which are found either upon the same or different plants, were long looked upon, even by botanists of the first eminence, such as Linnaeus, Jussieu, Decandolle, and Brown, as being true stamens and pistils. Hence the plants were placed in the phænogamic or vascular division of vegetables, and were referred to the classes *Monandria* and *Monœcia*. The structure and habits of the characeæ, however, seemed to differ so much from those of the true flowering plants, that doubts were for a long time entertained as to the propriety of referring them to that division of the vegetable kingdom; and a more careful examination has led most botanists to believe that they ought to be considered a distinct order of cellular vegetables. In consequence, however, of the peculiarity of their organisation, it is not easy to trace their affinity to other cryptogamic tribes, and considerable difference of opinion at present exists on the subject. Professor Lindley considers them as allied to *Conferveæ*, but has placed them amongst the *Muscoideæ*, or moss-like plants; while Dr. Hooker, has placed them beside the *Algæ* or sea-weed.

The chara tribe are remarkable on account of many of the species emitting a very disagreeable fetid odour, which does not seem to be dependent on the water in which they grow.

They are generally of a dull greenish colour, and have roots, which are usually attached to the bottom of stagnant pools of fresh or salt water. Their stems are delicate, slender, and sometimes jointed. They are frequently rendered hard and brittle by encrustations of carbonate of lime, which are formed on the

outside of the central tube, and are covered by a fine transparent membrane. These encrustations are not mere accidental deposits, depending upon the presence of some extraneous matter in the water in which the plants grow, but are formed by the vital energies of the plant, and probably perform an important office in the processes of vegetable life. The particles of calcareous matter, when carefully examined under a high magnifying power, exhibit various beautiful arrangements, at one time extending in the form of parallel lines along the stem, and at other times forming oval groups, which are attached to each other like the beads of a necklace. While examining these in the *Chara vulgaris* and *hispida*, Sir David Brewster found that the plants became phosphorescent when placed on heated iron, so as to display their entire outline in the dark. He also ascertained that each mass of calcareous matter consisted of minute particles, which possessed double refraction, and had regular neutral and depolarising axes.

An important and highly interesting physiological phenomenon has been noticed in some of the chara family by Professors Amici and Blainville. On examining the stems of some of the species, more especially the *Chara vulgaris*, they observed two liquid currents, one ascending, the other descending, circulating in the same tube, without being separated by any partition which could insulate them. The reality of this phenomenon was completely confirmed, by their observing distinctly that certain molecules of one of the currents, being attracted by the other moving in an opposite directing, were sometimes carried along with it. The rate of motion is stated to be about two lines in a minute. The motion is stopped by pressure, laceration of the tube, or by the application of a drop or two of brandy.

The characeæ are met with in all regions of the globe, in Europe, Asia, Africa, and America, but they are most abundant in temperate countries. Some of the species found in Iceland are said to grow even in the hot springs of that island.

Nucules of charas, under the name of *Gyrogomits*, are found in the marl deposits of the Forfarshire lakes, and in the chalk of Montmartre. From these fossil remains, it would appear that the characeæ were formed more recently than the ferns and palms.

Trout are said to thrive well in water where charas grow, probably on account of these plants attracting a great number of insects.

The characeæ do not possess any particular known properties which would render them useful either in a medical or economical point of view.

The only genera of the order are *Chara* and *Nitella*. The latter genus is said to differ from chara in being always transparent, and free from calcareous matter, in having a single-jointed stem, and the globules and nucules on separate plants. These characters are, however, by most botanists not considered sufficiently constant, and the two genera are therefore generally described under the common name of chara. There are eight species natives of Britain, and of these *Chara translucens* is the largest and brightest coloured. *Chara vulgaris*, from its roughness, is used, like some species of equisetum, for scouring or polishing.

**CHARADRIUS—Plover.** A very interesting genus of birds, belonging to the order *Grallidæ*, of which the details will be found under the article **PLOVER**.

**CHARICLEA** (Stephens). A beautiful genus of lepidopterous insects belonging to the family *Noctuidæ*, and having for its type the rare peach blossom moth of British collectors, *Noctua Delphinii* of Linneus. The anterior legs are armed at the extremity of the shanks with two shining horny spines; the wings are very gaily ornamented with purple markings, and are about an inch and a quarter in expanse.

**CHARLOCK** is the English name of the *Sinapis arvensis* of Linneus. It is a tetradynamous annual, and belongs to the natural order *Cruciferae*. No weed, except the thistle perhaps, gives the English farmer more trouble, nor causes more injury to his crops, than this. It springs up with, and ripens seed before the corn; consequently much seed is scattered on the ground by the sithe and sickle in gathering the crop. Although an annual, it is not easily extirpated, as the seed will lie uninjured in the soil for years; and when the farmer has lost sight of it for several consecutive seasons, it will at last come up so abundantly, that the crop of corn will be choked by the plant, and covered with the yellow flowers of the charlock.

**CHARLWOODIA** (Sweet). A genus of ornamental trees, natives of New Holland and New Zealand, named in honour of G. Charlwood, F.L.S., an intelligent English botanist. Linnean class and order *Hexandria Monogynia*; natural order *Asphodeleæ*. Generic character: calyx bell-shaped, regularly six-cleft, withering; stamens inserted in the throat of the corolla; filaments awl-shaped, smooth; anthers versatile, cleft at the base; style filiform; stigma three-lobed; berry globular, three-celled; cells full of seeds. There are four species described; two are common in our collections, "one with pale purple, another with blue flowers; they should be kept in a very warm greenhouse, as they are tender, or in a cool part of a stove, and may be increased by cuttings of the young side shoots. The cuttings must not be deprived of their leaves, but put into pots filled with an equal mixture of light loam, moor earth, and sand; which compost is also the best soil to grow them in." *Sweet*.

**CHARÆAS** (Stephens). A genus of lepidopterous insects belonging to the family *Noctuidæ*, having the wings more or less notched; the palpi are very short, and the antennæ of the males more or less comb-shaped. The genus includes five British species which vary considerably in structure, amongst which the *Phalæna bombyx graminis*, Linneus, or the antler moth, is placed. This insect is exceedingly destructive in pastures, feeding upon grass; and it is recorded that in Sweden, towards the middle of the last century, its ravages were so extensive that whole meadows appeared white and dry, as though a fire had passed over them. In England also, at various but uncertain periods, different parts of the country, especially the northern counties, have suffered from its ravages, "spots of a mile square were totally covered by them, and the grass devoured to the root." Mr. Wailes has recently published some interesting observations upon this insect in the Entomological Magazine, noticed upon Skiddaw: at least fifty acres of which were so completely devastated and the line of devastation so clearly marked, that even from the town of Keswick the progress of the larvæ down the mountain could be distinctly noted. Vast quantities of rooks flocked to the spot to feed upon the delicious repast afforded by these caterpill-

lars; but so greatly was the vegetation destroyed, that even several years afterwards the extent of their ravages was distinctly visible. "Of course," adds Mr. Wailes, "the quality of the newly-grown herbage was materially improved, thus affording another instance of indirect advantages derived from insects;" and Mr. Haworth in like manner observes, "Perhaps this apparently destructive scourge of the Swedish pastures (though happily not of our English ones) is of more use in the great economy of nature than we are aware of, by preventing the almost total suffocation and consequent destruction of the flowering plants, in giving them an occasional season in which they may recover themselves to become the food, the necessary food perhaps, of many insects, &c., which would perish whenever that became extinct."

The caterpillar is of a brown colour with yellowish streaks on the sides and back. In the month of June it changes to a shining brown chrysalis, and the moth appears in about a fortnight, being of a brown colour, and having a long pale line along the upper wings united to two large pale spots in front, and branching behind into three oblique teeth. We have, however, met with it later in the year, having captured it at the middle of August, both upon the Wrekin in Shropshire and Snowdon. It seems indeed to frequent mountainous districts, and contrary to the general habits of the family, we noticed it flying with great velocity in the middle of the day. We mention this because Mr. Wailes has stated some curious facts to which it is opposed. He noticed these insects one morning, about eight o'clock, flying in swarms over old pastures; on returning to the spot, a couple of hours afterwards, with his fly-net, not one was to be seen. The next morning, however, he was early on the spot, but then also not a solitary moth was to be seen; at half past seven he was about to return, "when suddenly the whole field, as far as the eye could reach, was once more the scene of their gambols, the eye became bewildered with their motions, they were lost in the mazes of their evolutions. Sudden, however, as their appearance had been, their disappearance was equally so, as with one general consent at about half past eight they again settled, and their flight for the morning being over, scarce a solitary specimen was any where to be seen. The moths flew about three or four inches from the ground, and apparently very seldom alighted, but threaded their way most dexterously amongst the long culms of the grasses."

**CHAULIODUS**. A genus of soft finned fishes with abdominal fins, belonging to the pike family. There is only one known species, an inhabitant of the waters of America, it is of a bright green colour, and about a foot and a half long, the muzzle is very short, but the gape extends as far as the eyes, and the teeth are strong and powerful, especially two crooked ones in each jaw; its habits, and, indeed, its characters are very imperfectly known.

**CHEESE-HOPPER** or **CHEESE MITE**. A small white fleshy grub of an elongated form, often found in decayed cheese, and which is the larva of a pretty two-winged fly known by the systematic name of *Piophilæ* (*Tyrophagæ*, K.) *casei*. Of this insect the immortal Swammerdam has left us an interesting account, and although to unthinking persons it may appear to be a frivolous subject of inquiry, we find this illustrious philosopher affirming "that the limbs and other parts of this worm are so uncommon and

elegant, and contrived with so much art and design, that it is impossible not to acknowledge them the work of infinite power and wisdom to which nothing is hid, nothing impossible." It has been a common error that these insects were bred spontaneously from the cheese, and epicures accordingly do not hesitate to eat them with great goud, thinking them formed from the best part of the cheese, whereas they are produced from eggs deposited therein by the parent fly. These larvæ are long, cylindrical, and composed of twelve rings, the first of which is furnished with two small bent hooks of a black colour, which serve not only as teeth, but for feet also, the insect having no other organs employed as legs. The terminal segment of the body is covered with a variety of prominent tubercles and little cavities like wrinkles, of which we shall presently see the use. In our article *CERCOPIDÆ* we have alluded to the leaping power of this insect, and our figure will give an idea of the manner in which it prepares to make a spring.

1, the cheese-hopper preparing to spring.  
2, the insect's natural size.  
3, 4, the fly to which it is transformed: natural size and magnified.

When this larva prepares to leap it first erects itself on its anus, in doing which it is greatly aided by the prominent tubercles of the terminal ring, which enable it to maintain an equilibrium. It then bends itself into a circle, and having brought the head towards the tail it stretches out the two hooks of the mouth, fixing them into the two cavities at the extremity of the body. It then contracts the body from a circular to an oblong figure, the contraction extending in a manner to every part of the body. It now suddenly and with very great violence lets go its hold, the noise produced by its hooks being very perceptible, and in this manner the leap is effected, being in fact similar to the mode employed by the salmon when they wish to pass over a cataract or salmon leap, as it is termed. Swammerdam saw one, whose length did not exceed a quarter of an inch in length, leap out of a box six inches deep, that is to a height more than twenty-four times greater than the length of its own body, but they will leap much higher. Here we cannot but admire the powers given by nature to different creatures, and their limitations, to answer different purposes, and not for mischief to mankind. If for instance a power of motion, proportionably equal to that possessed by this insect, had been given to the serpent tribes, how much more terrible would they not have been rendered then, than they are with their present capabilities? A viper would throw itself nearly a hundred feet upon the traveller, and the rattle-snake several hundred. Swammerdam, after giving a minute account of the external and internal anatomy of this creature, observes, "Now let the sharpest geniuses, and men of the greatest penetration and learning, judge if a creature on the fabric

of which there plainly appears so much art, order, contrivance, and wisdom, nay, in which is seen the hand itself of the Omnipotent God, could possibly be the production of chance or rottenness." The female fly is provided at the extremity of the body with a very fine retractile borer wherewith she pierces the cheese, and is thereby enabled to deposit her eggs in the wound thus made. Shortly after which the grubs are hatched, and feeding upon the cheese cause it to decay; the fine powder which we perceive, and which is so highly prized by the gourmand, being nothing else but the excrement of these grubs, which, when they have acquired their full size, desert the cheese, and in three or four days they lose all motion, grow stiff, become hard, and contract their bodies into an oval mass not more than half their previous length, within which the real pupa is inclosed, this insect undergoing the coarctate kind of metamorphosis, like the majority of dipterous insects. After remaining some time in this state, the chrysalis becomes of a black colour, and the inclosed nymph breaks that part of the outer covering which defends its head into two parts, and at the same time throws off from every part of the body a thin and slight membrane which it leaves within the old case. At first the wings are scarcely perceivable, the insect, however, runs about very quickly, and shortly afterwards the wings are by degrees extended until they assume their full size, when the insect is fitted for pursuing its duties, which almost entirely consist in the reproduction of the species. The fly is about the size of the common domestic fly, of a shining blackish green colour, the wings transparent and shining, and the legs varied with ochreous and black.

**CHEILODACTYLES.** A genus of spinous finned fishes, belonging to Cuvier's third family *Scenoides*, and bearing some resemblance to the perch family. They have the body oblong, the mouth small, numerous spinous rays in the dorsal fin, and the inferior rays of the pectorals continued in a membrane. There are several species, the greater number of which are inhabitants of the eastern seas.

**CHEILODIPTERA.** A genus of spinous finned fishes, belonging to the perch family. They are all of very small size, and found in the warmer seas of the east.

**CHEIMATOBIA** (Stephens). A genus of lepidopterous insects, belonging to the family *Geometridæ*, and remarkable for their appearance in the winged state in the depth of winter. Of these the type is the *Phal. geom. brumata* of Linneus, an insect of very plain appearance, measuring about an inch in expanse, of an ashy brown colour, with nearly obsolete darker waves. It is very common in the neighbourhood of London, and may be seen flitting about the leafless hedges at dusk or by lamp-light, in moderate weather.

**CHEIROPTERA**—winged hands. The first family, or sub-order, of Cuvier's great order *Carnassiers*, or mammalia, which feed upon animal matter. Their most remarkable characters, and the one from which they obtain their name, is that of having the extremities, the arms especially, furnished with membranes, by means of which the animals are enabled to fly; although, in a manner much more awkward than that of birds. A particular account of the action of those singular creatures, as well as of the habits of the leading species, has already been given in the article *BATS*. Hence it will be necessary, in this place, to

give only a synoptic table, for the sake of reference, to the different genera. There are two tribes in the family, the bats properly so called, and the flying bats; and the first admits of sub-division into two groups.

FIRST TRIBE.—Bats properly so called.

First group, chiefly animal feeders.

Genus 1, *Vampires*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{3}{3}$ . Canines in lower jaw angular, roots touching.

Genus 2, *Phyllostoma*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{3}{3}$ . Canines in lower jaw parallel.

Genus 3, *Glossophagus*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{3}{3}$ . Canines in lower jaw parallel.

Genus 4, *Morops*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{3}{3}$ . Inferior membranes very long, tail of mean length.

Genus 5, *Vespertilio*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

Genus 6, *Plecotus*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{3}{3}$ .

Genus 7, *Nycteris*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

Genus 8, *Rhinopoma*. Teeth; incisors  $\frac{2}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

Genus 9, *Molassus*. Teeth; incisors  $\frac{2}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

Genus 10, *Myopterus*. Teeth; incisors  $\frac{2}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

Genus 11, *Taphazous*. Teeth; incisors  $\frac{2}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{5}{5}$ .

Genus 12, *Noctilio*. Teeth; incisors  $\frac{2}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

Genus 13, *Nictivorous*. Teeth; incisors  $\frac{2}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

Genus 14, *Stenoderma*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

Genus 15, *Rhinolophus*. Teeth; incisors  $\frac{2}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

Genus 16, *Megaderma*. Teeth; incisors  $\frac{2}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{3}{3}$ .

Second group, in great part at least, feeders upon vegetable substances.

Genus 17, *Pteropus*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{3}{3}$ .

Genus 18, *Cephalotus*. Teeth; incisors  $\frac{2}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{3}{3}$ .

Genus 19, *Cynoptera*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{3}{3}$ .

Genus 20, *Harpya*. Teeth; incisors  $\frac{3}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

Genus 21, *Macroglossus*. Teeth; incisors  $\frac{4}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{3}{3}$ .

#### SECOND TRIBE.

One genus, *Galcopithecus*. Teeth; incisors  $\frac{3}{3}$ , canines  $\frac{2}{2}$ , grinders  $\frac{4}{4}$ .

In the above tabular statement, the whole of the incisive and canine teeth are mentioned, but only half the grinders, or those on one side of each jaw, the upper number referring, in all the statements, to the upper jaw, and the under number to the lower.

CHELIFERIDÆ. A family of small annulose animals, belonging to the class *Arachnida*, and to our order *Adelarthrosomata*, having very much the appearance of minute scorpions destitute of tails, the body being oval, depressed, and narrowed in front; the palpi as long or longer than the body, in the form of arms, each terminated by a double claw; the legs are of equal size, and short, being terminated by two hooks, and the eyes (two or four in number) are

placed at the sides of the thorax; the breast is not furnished with the remarkable toothed appendages to be observed in the scorpions. These animals, being destitute of lungs, breathe by means of lateral tracheæ or spiracles along the sides of the body. By Linnæus the only species of the family known to him, was at first arranged with the mites (*Acarus*), and afterwards with the harvest-men (*Phalangium*), from all of which however it is abundantly distinguished, and accordingly Geoffroy established for its reception the genus *Chelifer*, whilst Fabricius placed it amongst the scorpions. Illiger again, neglecting the step taken previously by Geoffroy, formed the genus *Obisium* for this group; and still more recently Dr. Leach has not only adopted the genus *Chelifer* of Geoffroy, but also that of *Obisium* for several of the species which differ from the true chelifers in some respects, a step which appears to us to have been improperly taken, as it is evident that Illiger's genus was strictly synonymous with Geoffroy's, both having the *Chelifer cancrroides* for the type.

As a family, these little animals are highly interesting in respect to the general distribution of the class to which they belong, exhibiting, as they do, the appearance of one group, whilst they in reality belong to another quite distinct. They are found, in general, in moist situations in moss under stones, flower-pots in gardens, and in unfrequented parts of buildings; they also get into old books, herbariums, &c., where they feed upon other more minute insects, such as *Atropos lignarius*, *acar*, and occasionally even venturing to attack the domestic fly, of which circumstance various notices will be found in the Magazine of Natural History. We have likewise captured the largest species, which we have hitherto seen of the group, under the bark of trees in Windsor forest, in the act of devouring even the hard-cased beetle (*Bitoma crenata*). Goetze also has fed them with aphides.

According to Linnæus, these animals occasionally introduce themselves beneath the skin, producing a painful swelling, and on the information of Dr. Bergius, he states that a peasant had his thigh pierced during the night by one of these insects, which formed by the morning a pustule of the size of a nut, which was very painful. These insects creep rather quickly, and will, when disturbed, run sideways like a crab. Roesel states that the female lays small eggs, of a greenish-white colour, which she forms into a mass side by side, and, according to the elder Hermann, she carries this mass about with her beneath the body, like some spiders.

The family comprises only the two genera mentioned above, of each of which there are various British species. The type of the family, *Phalangium cancrroides* of Linnæus, seldom exceeds one-eighth of an inch in length.

CHELONE (Linnæus). A genus of American ornamental perennial herbs, of late years introduced into our flower gardens. Linnæan class and order *Didymia angiosperma*; natural order *Scrophularia*. Generic character: calyx five-parted, persisting; corolla bell-shaped, bellying, limb two-lipped, the upper one two, and the lower three-lobed; stamens, rudiments of five, smooth or bearded; anthers incumbent and oblong; style bearing a headed or bilamellated stigma; capsule two-celled, two-valved; margins of the valves inflexed; seeds margined or naked. The chelones are pretty showy

plants, and all grow freely in any soil. They are easily propagated by cuttings, placed under a hand-glass.

**CHELONIA.** The first order of reptiles in Cuvier's arrangement. Some of them are land animals, and others aquatic; the former being known by the general name of tortoises, and the latter by that of turtles. They are all four-footed animals, or quadrupeds; and they are encased in a coat of armour, usually called a shell, and which adheres to the sternum and the ribs.

They have the heart with two auricles, but only one ventricle, though the latter is divided into two chambers or cells, by an incomplete partition, which admits of a communication between the one and the other. The blood, which returns from the circulation over the body, is received into the right auricles of the heart, and that from the lungs into the left; but owing to the imperfect division of the ventricle, the circulation is incomplete, as the blood which has undergone the action of the air in passing through the lungs, is in part mingled with that which comes from the body, and the mixture is returned to the system, so that only a portion of even that which passes through the heart is subjected to the renovating influence of the air in the lungs.

In all animals, even those which have the double heart most perfect, only a limited portion of the blood passes through the heart at each pulsation; and the inferior vertebrated animals, which have a slow circulation and low temperature, have only a portion of that which passes through the heart sent to the lungs; this portion being less and less in proportion as the general action of the system is more languid.

The structure of a chelonian reptile can be perhaps best explained by first attending to the most striking part of its external appearance, the double buckler in which its body is encased. This principally consists of two parts, a spinal and a sternal one; the first the shield on the back, and the second the breast-plate on the under part of the body. Both of these consist of a number of pieces, which varies in different species; and the forms of the plates, and the modes of their junction with each other, are the foundations of some of the trivial characters.

A row of these plates ranges down the back of the animal, and there are others ranged along the sides of these which, with them, form the disc of the shield. Of these there are sometimes as many as eight pairs; and towards the margins of the breast-plates they are surrounded by others, usually about from twenty-one to twenty-five, which form the margin of the shield. They are more irregular in their forms than the plates which compose the disc, and are generally oblong; the lateral plates are united by sutures to each other, and also to the dorsal plates, which last are fastened, but not soldered, to the vertebra. When the different plates or pieces which form the shield, rise in a sort of ridge in the middle, they are said to be *carinated*, or keeled; when they are depressed in the middle, they are said to be *furrowed*; when they rise uniformly to the middle, they are called *convex* or *sub-convex*, according to the degree of elevation; when they lie over each other like slates on a roof, they are *imbricated*; and when they have the margins toothed or jagged, they are *serrated*. The pieces which form the breast-plate or external buckler, are usually about nine in number. They are more or less firmly attached to the marginal plates of the

shield along the sides; and in general none of the parts which form these two bucklers, or are attached to them, have any motion.

There is one opening between the shield and breast-plate anteriorly, through which the head and fore extremities of the animal are projected; and another at the opposite end, for the posterior extremities and the tail.

The anterior extremity of the blade-bone is articulated with the shield, and there is a connexion with the opposite extremity, and the breast-plate is united by a connexion which bears some slight resemblance to a clavicle. Thus the extremities, which bear the weight of these animals, are not articulated directly on the spinal column, any more than they are in the higher orders of vertebrated animals.

In some species the terminal plates, or pieces of the breast-plate, are capable of a slight motion, so as completely to shut in the head and extremities, and protect them from the attacks of every enemy except man. Those which have this structure and motion of the shell are called "box tortoises."

In the greater number of the species, the motion of the extremities is exceedingly slow; but the power of moving other bodies is great in proportion to the slowness of the rate, for one of the larger land tortoises can get along at its sluggish pace, with the weight of two or three men standing upon its back. The vertebrae of the neck are beautifully articulated; and although the range of space over which it is capable of moving is very limited, there is perhaps no animal which commands with so much certainty and steadiness the space over which it can move.

There is a sort of frame-work of osseous pieces, which bears some resemblance to the sternal or cartilaginous portion of the ribs; but this has no motion, nor indeed is there motion in any part of the animals, except in the head and neck, the tail and the extremities.

The osseous portion of the chelonian is immediately covered by the integuments, the scaly plates on the skin, without any intervening muscles, which are all placed on the inside, so that in some respects these appear to be animals turned inside out, or at all events with the substantial part of the skeleton without side the organs of motion; and they are thus in some respects intermediate between the vertebrated and articulated animals. There is even a resemblance to birds, though a very slight one, in the articulation of the anterior extremity: there is a large bony haunch which extends backwards, from the articulation of what may be termed the humeral joint, and which, in form and position, bears some resemblance to the coracoid bone in the feathered tribes, only it does not abut on any solid support at its posterior extremity, either on the breast-plate, or on the bony frame-work above alluded to. It appears merely to afford the shoulder a more firm imbedment than it could otherwise have.

The lungs of the chelonian are contained in the same cavity with the rest of the viscera; as is the case in all reptiles, they extend into the abdomen, but they are separated from the abdominal viscera, properly so called, by a duplicature of the peritoneum. In consequence of the structure of the shelly covering, which precludes the possibility of breathing in the ordinary manner, by the action of an elastic thorax and a diaphragm, the breathing of the chelonian is very peculiar, and has more resemblance to a sort of

drinking than to ordinary breathing. The whole is performed by the action of the mouth, at least in all the species which have the scaly plates immoveable. The *os hyoides*, or bone of the tongue, is the principal organ of support in the performance of this somewhat curious process. When these creatures breathe, they do not open the mouth, as is the case with most of those animals which require a more frequent and copious supply of air. On the other hand, they keep the jaws firmly closed (and there are no animals which can close them more firmly), and perform the respiration by means of the action chiefly of the tongue. By depressing the *os hyoides*, they open the nostrils, and at the same time form an open cavity of considerable extent in the mouth, into which the air rushes. Then, when the cavity thus formed is filled with air, the *os hyoides* is raised, which closes the apertures of the nostrils, and at the same time, by lessening the cavity of the mouth, forces the air into the lungs, which of themselves perform the operation of expelling the air after it has performed its function.

It will be seen that this species of breathing has much more of a voluntary process than that of the higher animals, which require the operation much more frequently, and that thus it can be suspended at the pleasure of the animal. The same kind of respiration takes place in the *Batrachia*, and indeed to a greater or less extent in the whole class of reptiles. See REPTILES.

In the armature of their jaws the chelonia have some resemblance to birds, and indeed there are many more structural coincidences between the two than we would be prepared to expect in animals which are so different both in their appearance and their habits. Generally speaking, the jaws of the chelonia are covered with horny plates, not very unlike the mandibles of birds; but in the texture of this horny substance there appears to be a general law in the species—those which have the bucklers of the firmest texture have the coverings of the jaws firmest; while the soft tortoises, which have only a thick parchment-like skin for their covering, have the jaws covered with a similar skin. When we say “shell,” in the case of these animals, we must not be understood to mean shell properly so called, that is, shell containing salts of lime, which can retain their form after all the animal matter has been destroyed by burning; for even the most compact of their coverings, the shell of the hawk’s-bill turtle, the true tortoise-shell, of which so many trinkets, and other little ornamental matters, are made, approaches much more nearly in substance to horn than to any thing else with which we can compare it. The chief difference, indeed, is in the texture, which is not fibrous, but rather composed of small laminae, which admit of division with almost equal readiness in all directions. The substance to which it approaches most nearly is that of hoofs, more especially the hoofs of antelopes. But it is really horn, and can be softened and treated exactly in the same manner as other horny substances. There is a gradation in the production of horny substance, which is worthy of more careful examination and study than it has hitherto met with. The loosest texture with which we are acquainted is that of baleen, on the plates of whalebone in the large Greenland whale. This substance is little else than soldered hairs, and hairs not very closely or firmly soldered, as they can be very easily separated from each other, though even these are more easily

separated into plates than into fibres. From them there is a gradation; and it is not a little singular that we meet with the other extreme of the series in an aquatic animal, the hawk’s-bill turtle, and also that the firmness of texture in this substance appears to be in proportion to the sluggishness of living action in the animals in which it is found. It is also worthy of remark, that the animals in which this substance is found are tenacious of life, very much in the ratio of the firmness of the substance.

Perhaps when we consider the matter physiologically, we ought to be prepared for expecting this. The principle of life in animals, of what class soever they may be, is a principle at variance with or opposed to the principle by which substances are brought into contact, and retained there—to all the attractions of gravitation and aggregation, in short; and we find that, in all animals, indeed in all organised beings, the departure from the common homogeneous structure, which matter, in obedience to those laws which have no principle of life in them, invariably assumes, is always in proportion to the energy of living action in the animal or the vegetable. The lowest, that is the least energetic in life, of vegetables and of animals are the most uniform and jelly-like in their structures; and the farther that we ascend in the scale of being, we find that there is always the more organisation. We find also that, in proportion as the organic being departs more from the ordinary laws of inorganic matter, it costs it the more labour to maintain the life. The higher animal must breathe frequently; and its blood cannot pass a second time into the circulation, or be able to perform its functions in the body, without being fully and freely exposed to the action of the renovating atmosphere; while, in those creatures in which life is less energetic, the action of a limited portion of the blood suffices, and even that may be suspended for a considerable time at the will of the animal, and is all but entirely suspended when they are in a state of hybernation. Even when they are not in a state of absolute hybernation, these animals can be kept alive for a considerable time without respiration. Some of them have lived for at least a month with the jaws firmly tied together, and the nose sealed up with wax, in which state they of course could neither eat nor breathe. As they have not much free action of air in the mouth, they have little voice, and the little which they do have is a sort of murmuring hiss produced by the violent compression of the lungs by those abdominal muscles which they use in expelling the air from these organs.

In the mode of bringing forward their eggs to the period when they are fit for deposition, these animals have some resemblance to birds; but the albuminous or white part of the egg does not coagulate with heat. The covering of their eggs also differs considerably from that of the eggs of birds, the hardest having more resemblance to indurated parchment or vellum than to common egg-shell.

Though some of them are inhabitants of temperate climates, and many take up their abodes chiefly in the waters, or in muddy places where the temperature is always low, yet they are all unable to bear extremes either of heat or of cold; and there are certainly few species which do not, during some part of the year, seek the mean temperature by digging into the earth, or burrowing in the banks. It is even probable that some of the marine species plunge to a considerable depth at some seasons of the year, and remain there,

suspended in the water, in a state of total inaction. The repose of the inhabitants of the sea is rather an obscure subject; but it is tolerably well ascertained that several species of surface fishes remain for a time suspended at considerable depths; and we know that several batrachian reptiles, the common frog for instance, spend their winter in the crevices of springs, entirely cut off from the atmosphere. While in this state they have the mouth and also the nostrils completely shut, so firmly that the mouth cannot be opened without almost a fracture of the jaws, until the animal regains its sensibility; and hence the popular opinion that, during a certain part of the year, the lips of frogs grow together, so that when they cease to feed they cease to have any opening of the mouth.

The chelonia resemble batrachian reptiles in several particulars, and in none more than in the form of the mouth, and the force with which they can close the jaws upon each other. Their temporal muscles are indeed remarkably powerful; and though a common turtle has no teeth, it can bite a pretty thick rope easily in two, or tear it in pieces. From what is known of the length of time that they can live exposed to the atmosphere with the mouth closed and the nostrils shut up, it is reasonable to conclude that they are capable of living much longer in the water in the same inactive state. Not only the shelly covering, but the whole of the integuments of the marine chelonia are better adapted for resisting the action of water than that of the atmosphere; and this is another reason which renders it at least probable that they follow the general law of the family in hibernating for a portion of the year. Many of their general properties are, however, common to the whole class, and can be more briefly as well as more clearly explained in the general article. We shall therefore devote the remainder of the few remarks to be made here to some notice of the several genera or sub-genera, into which naturalists have divided the family.

**SEA TORTOISES, OR TURTLES (*Chelonia*).** The species included in this genus are the largest in size, and some of them are the most valuable to man in the whole tribe. They have their shell too small for allowing the head and extremities to be entirely withdrawn within it. Their feet, especially the anterior ones, are much longer than in the land tortoises; their terminations are flattened, and the toes united by membranes, so that they form a sort of fins or swimming paws. The two first toes of each foot have pointed nails, which are liable to drop off at a

between them. The marginal pieces are in part separated from each other, so as to form a series of lobes which correspond in number to the sternal ribs. From this peculiarity of structure, these animals are not perfectly rigid; their bodies "give" a little, which of course assists them in making their way through the water. This genus contains seven or eight known species, of which we shall mention only some of the more important.

**CHELONIA MYDAS**, common green Turtle, or eatable turtle. Of all the chelonian reptiles, this is deservedly held in the highest esteem, from the very nourishing and palatable food which it affords to the human race. It is also one of the largest of these tribes, and it is not less interesting from its habits and manners, than from its utility as an article of diet.

A full-grown turtle often measures six or seven feet in length, from the nose to the tip of its short tail, three or four feet in breadth, and nearly as much in thickness at the middle of the body. It sometimes weighs eight hundred pounds. The body appears of an oval form, and the head is of considerable size in proportion to the body. The tail is short and thick. The feet are long, and much better adapted to the action of swimming than that of walking. The head, feet, and tails, are covered with scales. The breast plate is shorter than the shield, and has twenty-three or twenty-four plates disposed in four rows. The prevailing colour of this turtle's shell, when in its usual situation, is bright brown, with spots of a yellow colour, and when the shell becomes dry, the brown assumes a darker hue.

This species frequents the coasts both of the islands and continents of the inter-tropical regions, and is found in great abundance both in the East and West Indies. It sometimes enters the mouths of large rivers, and occasionally goes to some distance from the shore, into the sheltered woody parts of the country. It swims with great facility, keeping its head and part of its shell above the surface of the water; but when it fears the approach of danger, or seeks its prey among the rocks, it dives to the bottom, and may be seen browsing at its ease among the weeds. It is said, however, that it does not dive very readily, as the specific gravity of its body but little exceeds that of the salt water. When it quits the water, its motion on the land is rather a scramble than a walk, and resembles that of seals and walruses among quadrupeds, except that it is much slower.

The great purpose for which turtles go on shore is to deposit their eggs in the sand. This process is generally begun in the month of April, and takes up several weeks, as the eggs are laid at intervals of about fourteen days. When preparing to lay her eggs, the female turtle digs a hole about two feet deep, a little above high-water mark, and into this cavity she drops about a hundred eggs at one time. While thus employed, her attention is so completely taken up with the business for which she has come on shore, that a person may easily approach her from behind and catch the eggs as they are let fall; but if disturbed before she begins to lay, she quits the place, and seeks a more secluded spot. After having deposited all the eggs which she is to lay at one time, she scratches the sand over them, and leaves them to be hatched by the heat of the sun. The eggs of this species are round, about the size of a tennis ball, and covered with a white skin resembling parchment. It is said that that part of turtles' eggs, which is analo-

certain age. The different pieces of which their shield is composed do not join each other by sutures, so as to form a continuous shell, like that of the land genera, but have portions of cartilaginous substance

gous to the albumen or white in the eggs of birds, does not coagulate by the heat of boiling water.

As the female turtle lays her eggs at three or four times, with intervals of about a fortnight, the young are of course hatched at different periods, the eggs of each laying require about three weeks before the young are ready for extrusion. The little animals are of the same shape with their parent, but have only a soft covering instead of a shell. As soon as they are released from their confinement, they make directly for the water; and though this be sometimes at a considerable distance, they shape their course towards it in a straight direction. But a small proportion of them, however, in general reach their natural habitation. Great numbers of them are seized by various predacious animals, especially cormorants and other large birds, which hover about the shore from May to September, for the purpose of seizing such a desirable prize.

The individuals of this species are often found collected into numerous groups, though it does not appear that they have much enjoyment of a social intercourse, but are rather attracted to the same place by the abundance of their natural food which it affords. During the coupling season the male and female seem warmly attached to each other, and are said to continue together for near a fortnight.

To what age the green turtle is capable of living, were it to remain unmolested, cannot be ascertained; but it is conjectured, by those naturalists who suppose the age of an animal to depend upon its size, and the number of years required for attaining its full growth, that this species must live for at least a century. We shall see hereafter that this is no uncommon age for species of a much more diminutive size.

Even in the time of Pliny, the taking of turtles for the tables of the great was practised in the East Indies; and if we may credit the accounts of Ælian and Diodorus Siculus, the barbarous nations of the East were accustomed to employ the shields of the largest individuals as canoes. It is believed that it is only within these hundred and twenty years that turtles have been imported into Europe for the purposes of food.

Various methods are resorted to in different countries for catching turtles. A very common mode is, to watch them as they go on shore or return during the season of laying their eggs, when they are easily arrested, and, by the united force of several persons, are turned on their backs, a position from which they find it extremely difficult to escape. Several individuals are thus turned, and when a sufficient number has been thus partly secured, they are dragged away by ropes, and carried in boats to their place of destination. This is the method practised by the inhabitants of the Bahama islands, and is often employed with success by sailors while touching at the islands between the tropics during their long voyages. Turtles are also taken while swimming in the sea. Some fishers of great dexterity dive for such as they see at the bottom in the shallows, and, getting on their backs, press down the hind part, and raise the fore part of their body, so as to compel them to rise to the surface, when an assistant is ready to slip a noose over the head, and thus secure the captured animal. The most common mode, however, of catching turtles out at sea, is by means of a kind of spear, or harpoon, with a long

wooden shaft, to which the head of the spear is but loosely attached. This kind of fishing, as it is termed, is generally carried on by two men in a small light boat or canoe. One of those persons manages the boat, while the other stands ready to dart the spear into the back of his destined victim. It is not long before a turtle is seen either swimming at the surface, or, what is more usual, feeding at the bottom, when the water is about a fathom deep. Sometimes the animal discovers the approach of his enemies, and endeavours to escape, but the men paddle after him, and generally contrive to tire him out in about half an hour's chase. The spearman then hurls his weapon, the head of which, from the peculiar construction of the instrument, generally sticks fast in the shell, while its attachment to the shaft is secured by a long string. The animal, thus wounded, again makes off, unless he has been so much fatigued in the chase as to be incapable of further exertion. In either case he soon becomes an easy prey to his pursuers.

It is only for its flesh that this species is so much esteemed, its shell being of no use. In many of the West Indian islands turtles are exposed in the open market, and a turtle-steak is there as common as a beef-steak in Britain. The flesh of the turtle is extremely nutritious, and is considered an excellent restorative in cases of debility and emaciation.

Green turtle are perhaps the most delicate, and certainly the mildest in their manners of the whole genus. They are, strictly speaking, inter-tropical animals, being rarely, if ever, found beyond the 20th degree of latitude in either hemisphere. Within their range, however, they are very plentiful, and afford an abundant supply of food to even the rudest tribes. The New Hollanders, in the northern parts of that island, which lie within the turtle latitudes, are very dexterous in the capture of them. For this purpose they make use of barbed pegs of very hard wood, which are loosely placed on the end of a pole of light wood of considerable length. This pole is made a little thick at the end, over which a loop of string is passed, the other end of which is firmly attached to the peg. This they throw as a spear, in the use of which they are extremely dexterous, and the peg, taking effect in the cartilaginous covering of the turtle, remains firm there, while the long handle disengages from the peg, but remains attached by the thread, and acts as a float which keeps the turtle close at the surface, so that they can paddle after it till it is completely exhausted, and so capture it with very little trouble. On the north-west coast of the same island, where the land is almost, or altogether barren, and no inhabitants have hitherto been seen, turtle come to the banks in great numbers for the purpose of depositing their eggs, and are captured by turning them on their backs, in the same manner as is practised at Ascension, in the South Atlantic, and at the Gallipagos islands, on the west coast of America.

It should seem that volcanic formations, and also coral reefs, have some peculiar attractions for these animals; and it is natural to suppose that they should, inasmuch as these are the elements of much greater fertility for those marine plants upon which turtle feed, in both of these, than those are in more earthy formations. Volcanic matter always contains a considerable proportion of salts or alkalis, and there is a good deal of animal matter in the substance of

the coral reef. These substances not only act as manures to the sea-weeds, but they serve to combine the earthy particles more firmly together, and thus a firmer hold is given to the vegetation. This is so remarkable, more especially on the reefs, that, after the lapse of a year or two, substantial rock, with thick vegetation upon it, may be found in places where the deep sea line could previously find no bottom.

*Chelonia caretta*, the hawk's-bill, or tortoiseshell turtle. The name of hawk's-bill is given to this species from the form of the jaws, which are produced, sharp at the terminations, and incurved so as to have some slight resemblance to the bills of birds of prey, and it is called, *par excellence*, the tortoiseshell turtle, because it is from this species that the fine tortoiseshell used for so many ornamental purposes in the arts is obtained. The plates or shells of some others are occasionally used, but they are very inferior both in colour and lustre, and thus they are employed only as veneers, through which a coloured ground may be seen.

The hawk's-bill turtle, though of considerable size, is much less than the preceding, the largest individuals seldom weighing more than three or four hundred pounds. The shield is of an oval, and almost heart-shaped form, slightly sinuated before, and narrowest behind. The disk is covered with thirteen plates, that are two or three lines thick, of a smooth surface, nearly transparent, lying over each other like tiles upon a roof. The five vertebral plates are of unequal size and figure, though each is ridged longitudinally in the middle. That nearest the head is very large and quadrangular, with a semi-circular margin anteriorly. The three next plates are hexagonal, and have their greatest length across the body. The fifth is pentagonal, with one angle directed backwards, and a little prolonged towards the tail. The eight lateral plates are very large, and of an irregular pentagonal figure. There are twenty-five marginal plates, which are so much imbricated as to give the sides of the animal a serrated appearance. The colour of all these plates is generally black, with irregular transparent shades of red or yellow—all of them together sometimes weigh from four to eight pounds.

We have been thus particular in describing the plates of this species, because they constitute its most valuable product. They form what in Europe is denominated "tortoiseshell," but which, by the inhabitants of the West Indies, is more properly called "turtlesell." The head and neck of the caret turtle are considerably longer than those of the green turtle, and the upper mandible projects so much over the lower, as to give the snout a distant resemblance to the bill of a bird of prey, whence English sailors have given it the name of hawk's-bill.

This species is found in the Asiatic seas, and on

the Atlantic coasts of America, but is said not to be met with in the South Sea.

Though so much smaller than the green turtle, the hawk's-bill possesses considerable strength; and when attacked, defends itself with much ferocity, giving very severe and painful bites. It is also more difficult to secure, as its shield is more convex, and its feet longer than those of the first species; so that when turned on its back, it more readily regains its natural position. The female begins to lay her eggs in May, and continues, with intervals, till July. She is said not to deposit them in fine sand, but in gravel mixed with shells. The young of this species very nearly resembles those of the former.

The eggs of the hawk's-bill turtle are esteemed very delicious; but its flesh is unwholesome, and affects those who eat of it with fever and dysentery. It is almost entirely for the plates of tortoiseshell that it is made an object of search.

The use of tortoiseshell was known to the ancients, but it is only in modern times that the manufacture of it has been brought to perfection. In selecting the plates, those are preferred which are thick, clear, and transparent, and variegated with dark brown, golden yellow, red, and white. In preparing them for use, the plates are softened in warm water, and then reduced to the desired shape, by pressing them in warm iron moulds. After they are cooled, they are taken from the mould, smoothed and polished. For the purposes of inlaying in cabinet work, the moistened plates are pressed perfectly flat, and kept in that state till cool and dry. It is usual to place below them metallic leaves of such a colour as it is wished should appear through the transparent part of the shell.

In the Indian and Chinese seas the hawk's-bill turtle is very plentiful; and it forms one of the principal objects of the Malay fishery, which is carried on through all the eastern archipelago, and along the north-east coast of Australia. As this species is valuable only on account of its shell, it is not sought after except by nations which carry on trade; and, indeed, the capture of it requires a little more dexterity than that of the eatable turtle. It is also very abundant in many parts of the West Indian seas, more especially in the gulf of Honduras, where great numbers are captured. It is sometimes said, that the shell is inferior in the western world to what it is in the eastern; but it does not appear that there is much truth in the saying.

*Chelonia Caouanna*, the loggerhead turtle. This species is much more discursive than either of the two former, and also occurs in higher latitudes. Its colour is more or less of a reddish brown; five plates in the middle of the shield have an elevated crest in the centre; the point of the upper jaw is curved; and the legs are much longer and straighter than in either of the two former species. It is a powerful animal, and very enervetrical in all its actions.

It is a large species, and is said sometimes to exceed the green turtle in size. Its head is much larger in proportion than that of either of the former species. The mouth, and especially the upper mandible, is also of considerable size. The neck is thick, and covered with a loose wrinkled skin, thinly beset with horny scales. The shield is of an oval form, narrowest behind. It is of a yellow colour, with black spots. The legs, especially the fore legs, are proportionably longer than in many other species; and both

the fore and hind feet are furnished with two sharp claws.

The individuals of this species are most abundant in the tropical seas, especially about the West India islands; but they are also found in the Mediterranean particularly on the coasts of Sicily and Sardinia.

In its manners, this is one of the fiercest of the chelonian tribe; it defends itself with great courage and activity, both with its mouth and claws, and has been known to snap a moderate-sized walking-stick with a single stroke of its jaws. It appears to be the most predacious of all the turtles, not only feeding on shell fish of considerable size, the habitations of which it easily breaks with its strong mandibles, but attacking the young crocodiles, seizing them by the tail as they retire backwards into the water. Thus these annuals instinctively perform an act of retributive justice. The older crocodiles make a prey of the eggs and young of those turtles which inhabit the shores to which they resort, and the turtles in return seize on the young crocodiles while they are too weak to defend themselves.

The loggerhead turtle wanders very far from land. It has been seen apparently sleeping on the surface of the ocean, about midway between the Azores and Bahama islands, at a distance of many hundred miles from land. The female lays her eggs in the sand.

The flesh of this species is coarse and rank, and eaten only by the lowest classes of the people. Its body, however, affords a considerable quantity of oil, which is used for burning in lamps, and dressing leather. The plates of its shell are too thin for most purposes, but have been employed in cabinet work.

*Chelonia coriacea*, the leather-coat tortoise. There are several varieties of this species, all inhabitants of the sea, and some of them found at least occasionally in the Mediterranean. Their shield, even on the back, is flexible and leathery, and they have no plates even on the under part. Their flesh is not eaten, neither is there any part of them used in the arts; but it is necessary to attend to them with some care, as they have been confounded with some of the fresh-water tortoises.

**GENUS II. TORTOISES (*Testudo*).** These admit of division into several genera or sub-genera, according to their appearance and habits; and the species are very numerous, so much so, indeed, that we shall not attempt even to give a list of them. There are at least between fifty and eighty species, about thirty-six of which live generally in the fresh water, and the remainder generally upon land; but both of them hibernate in the mud or earth.

The fresh-water tortoises have all the toes separated, and generally a crooked claw upon each, though they are generally more or less webbed, or united by loose membranes. They have five toes on the fore feet, and four on the hind; and the feet are adapted both for swimming and walking. Their principal food consists of insects, small aquatic animals and fishes, and some of them eat voraciously, though all are capable of long abstinence. Some of them have the shell more and some less consistent.

*European fresh-water Tortoise (*Testudo Europæa*).*—This species is very common in the south and east of Europe, and is found as far to the northward as Prussia. It grows to the length of about ten inches. Its shield is oval, not much convex, nearly smooth, of a blackish ground colour, and spotted over with yellow points

disposed in rays. Its flesh is eatable, and it is sometimes fed with bread and green leaves, but it also eats insects, common slugs, and small fishes. It is sometimes made use of for clearing gardens of molluscous pests; but it does not thrive unless the garden contains a pond of water, and if there are fish in the pond, it is very apt to lay them under contribution. Its general progressive motion is very slow, but its neck admits of rapid motion, and, indeed, the neck is the grand organ of motion in the whole order. The other fresh-water tortoises are chiefly met with in the warmer regions of the world, though they have more range in latitude than the sea turtle.

Some of them have no scaly plates either on the shield or the breast-plate, but are supported entirely by the bones. They have in general their ribs produced on the margins of their covering, so as to form a border which is partially moveable, and of considerable assistance to them when they swim, which they do in shallow waters and among aquatic plants, where it is more difficult to make way than in the haunts of the sea turtle. They are also among the most active of the order; and though they have not the strong protection of the horny shell, they are endowed with a degree of activity and courage, which much more than compensates. They are all inhabitants of the fresh waters; and, with the exception of those in the sea, they are the largest animals of the order. We shall mention only the two principal ones.

*Soft Turtle of the Nile (*Testudo triunguis*).* This species is found principally in that river from which it derives its common name. Its colour is green spotted with white, and the shield on its back is a little convex. It is an active animal, preying on young crocodiles, of which it destroys great numbers. It sometimes attains the length of three feet or upwards.

*Fierce Tortoise (*Testudo ferox*).* This is the most formidable of all the tribe; and as it has been confounded by some writers with the coriaceous turtle, it is necessary to attend to the distinction between them. The coriaceous turtle has an oblong body, covered immediately with a bony shell; but that shell is invested with a tough membranous coat resembling leather, plaited longitudinally, and the shield terminates behind in an acute point, overhanging the tail. The body of the fierce tortoise is rounder and more convex, and the middle part of the shield is hard; but its margin, especially towards the tail, is soft and pliable, resembling thin sole leather, and the hind part is rounded. The tail of the first species is long, and very thick at the root; that of the second very short and small. The head of the former is small, round, and terminates in a beak, resembling the bill of a bird; that of the latter is proportionally larger and longer, with a long tapering cylindrical snout, having some resemblance to that of the mole. The coriaceous turtle is an inhabitant of the sea, is frequently found in the Mediterranean, and has been seen even on the coast of Britain. The fierce tortoise has yet been found only in the rivers and fresh-water lakes of America, especially in Florida and Carolina. The former is a large species, often measuring above seven feet in length; the latter seldom weighs above seventy pounds.

The fierce tortoise frequents lakes and muddy rivers, and hides itself among the water plants that

grow at the bottom, from which it is said to spring suddenly on its prey. This consists of small water animals, and in some places, more particularly of young crocodiles, of which this species is extremely fond. They seize their prey by suddenly darting forward their long and strong neck, which they do with great celerity.

This species is among the strongest and most active of its tribe, and as its trivial name implies, is possessed of ferocity and courage. When attacked, it boldly defends itself, rising on its hind legs, and leaping forward to seize on its assailant; and if once it fixes with its jaws on any part, it is scarcely made to let go its hold without cutting off its head. Though the fierce tortoise does not form so extensive an article of commerce as the green turtle; and perhaps on account of its activity, does not accumulate the soft and luscious green fat which epicures prize so much, yet its flesh is wholesome and is eaten with avidity, especially by the Indians in those parts of America where it is most abundant.

*The Mud Tortoise (Testudo lutaria).* The mud tortoise is the smallest of the fresh-water tortoises; its whole length, from the snout to the tip of the tail, seldom exceeding eight inches, while in breadth it is not more than three or four. It is of a blackish or dark brown colour. Its tail is nearly half the length of the shield, and is stretched out when the animal walks. Hence the mud tortoise has been sometimes called by the ancients *mus aquatilis*, or water rat.

This is a very frequent inhabitant of lakes and muddy rivers in the south of Europe, and in many parts of Asia. It is very plentiful in France, especially in the provinces of Languedoc and Provence. It lives almost entirely in the water, only going on land to lay its eggs, which it covers with mould. It moves with a quicker pace on land than many of this tribe; when disturbed it utters a kind of interrupted hissing sound. It feeds on fish, snails, and worms, and often proves a troublesome inmate in fish ponds, killing many of the fish, and biting others till they are nearly exhausted from loss of blood.

It has been proposed to employ the mud tortoise for destroying vermin in gardens; but it is necessary to have a pond or large vessel of water for its ordinary residence. With such a convenience, it may be rendered tame and domestic.

The young of this species, when first hatched, are not an inch in diameter. They continue to grow for a long time, and are known to live for many years.

There are many other species of tortoise, which inhabit the fresh water, of which we shall only mention the *Painted Tortoise (Testudo picta)*, which is an American, and a very handsome species, at least in so far as colour is concerned. It is smooth, of a brown colour, and each of the scales is surrounded by a yellow band, which is broader at the anterior edge than any where else. It is found in North America chiefly, and is more active than many of the others, often climbing rocks, and even trees, in search of insects, which constitute the principal part of its food; but the moment that it is observed, it drops into the water, and so escapes.

The land tortoises have in general the shell harder, and thicker in proportion to their size than any of the aquatic ones. In this way they follow a very general law of all animals, part of which inhabit the land, and another part the water; for even the bones

of aquatic animals contain a much smaller portion of salts of lime than those of the most nearly allied species which dwell upon land.

The land tortoises have the shield on the back supported by a frame-work of bones, which is united into one solid structure, so as to admit of little or no motion in the several parts; and the sides of it are in great part firmly soldered to those of the breast-plate, the whole forming a complete sheath of immense strength. The legs are very short, and so are the toes, which have five on the fore-feet and four on the hind. The nails or claws are strong and conical, and well adapted for digging; but their motion is exceedingly slow. They can, however, move under the load of a much greater weight, in proportion to their size, than any other known animals. They are capable of living for a long time without food; and, indeed, they are the very models of animal endurance. They are inoffensive in their manners, and seldom or never attack any animal, except those insects, mollusca, and worms on which they feed, and many of them eat green vegetable matter. The greater number of them, and perhaps the whole, spend part of the year in a state of hybernation, and bury themselves in the earth for this purpose. They do not construct a burrow with an entrance, as is done by the burrowing mammalia, but fairly sink down the body, throwing the earth on the back as they descend. This process is performed very slowly, but the progress of it is abundantly sure. In the course of their digging the head and tail are drawn within the shell, for all of them have the capacity of bringing both these and the feet within that covering. Their ascent to the surface is rather a more curious matter, and one which cannot be so well observed, but it may be presumed to be performed by bringing the earth gradually under the feet, and forcing upwards the strong and convex shield, with that powerful action which enables them to bear so great a weight. Some of them have the power of enclosing all the moveable parts of the body entirely within the shell, by drawing firmly moveable pieces of the anterior and posterior parts of the breast-plate against the corresponding portions of the shield. Those which can do this are called *box tortoises*; and they shut their box with as much firmness as the whole race are capable of shutting their jaws. There are a good many species, but we must restrict our notice to one or two.

*The Common Land Tortoise (Testudo Græca).* This species seldom attains a foot in length. It is of an oval form, with a very convex shield, broader behind than before. The breast-plate is nearly of equal size with the shield, and is of a pale yellow colour, with a broad dark stripe down each side, while the middle part of the shield is of a blackish brown mixed with yellow. The head is small, and covered on its upper part with irregular scales; the mouth is small, the legs short, and the feet pretty broad, and covered with strong ovate scales. The tail is very short, scaly, and terminated at its extremity with a curved horny process. It seldom weighs above three pounds.

This species is entirely confined to the land, and prefers elevated woody situations. It is found in Europe, Asia, and Africa, and is very common on all the coasts of the Mediterranean sea, especially in Sardinia, Barbary, and probably in Egypt. It is not a little curious that, even in the warmer climates, this species regularly retires to its subterranean quarters during the winter months; thus proving, what we

have before remarked, that the hybernation of these animals does not depend solely on the degree of cold. It begins to bury itself in October, and usually makes a hole about two feet below the surface, where it continues till April.

The males of this species are in summer tolerably active, and very fierce towards each other. The female lays her eggs towards the end of June, depositing them in a hole, and covering them with sand or mould. They seldom exceed five in number at one time, and are of a white colour, and about the size of those of a pigeon. They are hatched towards the end of September, and the young, when first extruded, are scarcely bigger than walnut shells.

The individuals of this species live on roots, fruits, worms, and insects, the shells of which latter they easily break with their strong jaws.

It has sometimes been alleged that land tortoises do not drink; but this is not correct: they are, no doubt, abstemious in their drinking, as well as in their eating, but it is well authenticated that they drink water, and that they are even partial to milk. They are very long-lived creatures; and some of them, even when removed to a colder latitude than that of which they are natives, have remained healthy for upwards of a century. Their flesh is eatable, and forms an article of human food in Greece; and the Italians eat the eggs, though not the animals themselves, at least not generally. Several varieties of this species are described by systematic writers; but they differ little from each other, except in the markings of the shell.

The Indian tortoise is a large species, of which individuals have lived, at least for some time, in Britain. One species, presented to the Zoological Society of London, in 1833, measured along the curve of the back four feet four and a half inches; the length of its sternum two feet eight; the breadth of the same two feet one; its total weight two hundred and eighty-five pounds. This individual had lived seventy-seven years at Port Louis in the Island of Mauritius. A large specimen from Bengal, which had died at the gardens of the Society some time previously, enabled a more careful examination to be made of its anatomical structure; but the details of these are not exactly adapted for a popular work.

*The Geometrical Tortoise (Testudo geometrica).* This is a very beautiful small species. The shell is black, and the plates, though of considerable thickness, are flattened into regular discs, which are beautifully marked with yellow rays proceeding regularly from centres.

**CHELOSTOMA** (Latreille). A genus of hymenopterous insects, belonging to the section comprising the bees, *Melifera*, family *Apidae*, and sub-family *Dasygastres*, of Latreille, having the body very long, narrow, and nearly cylindric, with the mandibles advanced, narrowed, curved and notched at the tip; the labial palpi are composed of a single joint, and the maxillary palpi are three-jointed; the marginal cell of the upper wings is not narrow at its extremity, and the second abdominal segment of the males is furnished beneath with a curious horny tubercle, answering to which is a singular cavity, covered with satiny down near the anus; like the division to which it belongs, the belly is amply furnished with a coat of down in the females, which serves for carrying the pollen gathered by the insect, destined for the support of her progeny. These insects, when asleep,

roll themselves up somewhat like the wood-lice, the ventral horn fitting into the anal cavity above mentioned; they usually take their luxurious repose in the middle of a flower, whence the type of the genus has obtained the specific name of *Apis florissomnis*. An interesting account of the habits of this insect is given in the Entomological Magazine by Mr. Doubleday, of which the following condensed statement will not prove uninteresting to our readers. Although the male is a perfect sybarite, a mere voluptuary, the female is the very model of maternal industry, her whole life being spent in providing for her family. Here we may observe, that in this, as in numerous other wild bees, there are no neuters, upon which depend the whole labour of the community; indeed here no community exists, each bee is solitary, and each female has to undergo the task of forming and provisioning its own nest, with a sufficient supply of food for its young when hatched, which does not take place until the life of the parent has ceased, so that the young are deprived of that constant attendance, which the hive bees bestow on their progeny. The female chelostoma carefully selects a spot in the posts of trellice, or other out-door wood-work, preferring the sunny side of those parts which are quite dry and going a little to decay; she there pierces a hole nearly horizontally, about an inch in depth, then changing the direction, she proceeds perpendicularly, her powerful jaws being the only tools wherewith she gnaws her passage through the wood, kicking the saw-dust out of the hole, passing it from one pair of feet to the next. This burrow is nearly a foot long, and in it, when completed, she commences the construction of about twenty cells, which are to be filled with pollen paste, and in each of which a single egg is to be placed. As however in the construction of these cells, and the deposition of an egg in each, the bee must work upwards, it is evident that the lowest egg will be deposited first, and will consequently first arrive at the perfect state; and unless provision were made for this circumstance, the first-born bee would either be compelled to remain a prisoner, in its cell until its *upper* brethren had taken their departure, or it must make its way through the cells placed above it, which could not be done without detriment to the inhabitants. Now the bee, exhibiting as striking an instance of that principle which we call instinct, as is to be found in any animal whatever, pursues a plan, not indeed by the operation of any thinking foresight, and still less being the result of education, which amply provides against this emergency, by again changing the direction of her burrow, at the bottom of the perpendicular part, so as to emerge again out of the paling. She then closes the hole just above the lower bend by a partition of fine sand, firmly glued together by means of a viscid saliva, with which she is copiously furnished; then laying at the foot of the enclosed part a sufficient quantity of pollen mixed with honey from the nectaries of flowers, for the support of one larva, in the midst of which she places a single egg, and closes the cell in the same manner as she found its bottom. In this manner she proceeds till she has reached the top of the perpendicular part. The two orifices of the burrow are then closed up, the lower one with a mixture similar to that employed in the division of the cells, offering of course but little resistance to the force of the bees when arrived at the perfect state. The upper one, however, being more exposed to danger from rain

which might enter, and getting into the nest, destroy the young larvæ, is first closed in the same manner as the bottom one, to which is added a layer of much larger grains of sand, glued together in a similar manner, each being fixed in the most convenient place by the assistance of the mandibles. Notwithstanding all her care, however, various parasitic insects contrive to deposit their own eggs in the cells in the absence of the parent bee, the progeny of which, of course destroys that of their fosterer, amongst which the *Chrysis cyanea*, the *Ichneumon manifestator*, and the *Fænus jaculator*, have been observed by various authors. The insect whose proceedings we have here described, varies in length from one-third to half an inch. It is not uncommon, and is of a black colour, with ashy hairs; the female, which is the *Apis maxillosa* of Linnæus, has the segments of the abdomen margined with white.

**CHENOLOBIA** (Leach). A genus united to that of *Coronula*.

**CHENOPODEÆ**—Goosefoot family. A natural order of dicotyledonous plants, containing nearly thirty genera, and upwards of two hundred species. It is so closely allied to *Amarantaceæ* that, although the orders are quite different in general habit and appearance, still, it is not easy to get any constant distinguishing characters. Professor Lindley justly declares, that though he is unable to give any good artificial distinctions, he at the same time cannot hesitate to keep asunder orders which nature has obviously divided. This order, which was denominated by Jussieu *Atriplices*, has also an affinity to *Phytolacææ*, from which it is separated by the stamens never exceeding the segments of the calyx, and being opposite to them.

The essential characters of the order are: perianth monophyllous, deeply divided, sometimes tubular at the base, persistent, with an imbricated æstivation; stamens inserted into the bottom of the perianth, and opposite to its segments, equal to them in number or fewer; ovary single, free, rarely cohering to the tube of the perianth; one ovule fixed to the bottom of the cavity of the ovary; style two to four cleft, rarely simple; stigmas undivided; fruit membranous, sometimes berried; embryo curved round a mealy albumen, or spiral, or doubled together, without albumen; radicle next the hilum.

The plants belonging to the order are herbs or low shrubs, with alternate, sometimes opposite, leaves, without stipules, and small, occasionally polygamous flowers. They are generally distributed over the globe, more particularly in extra-tropical temperate regions, and are found abundantly in the northern parts of Europe and Asia.

In general they are weeds which are not remarkable for their beauty, and are not esteemed as ornamental plants; several of them are avoided on account of the disagreeable odour which they emit. Nevertheless, many of the species are highly useful to man, some being cultivated as pot-herbs and articles of food, others being used medicinally on account of their tonic properties, and others again being valuable in a commercial point of view, on account of the alkaline substance which they furnish. They are propagated by cuttings, divisions and seeds. Some of the chief genera of the order are, *Chenopodium*, *Atriplex*, *Basella*, *Beta*, *Salsola*, *Salicornia*, *Bitum*, *Spinacea*, and *Camphorosma*.

The genus *Chenopodium*, goosefoot, whence the

name of the order is derived, furnishes nearly thirty species, thirteen of which are natives of Britain. They are succulent weeds, the leaves of which are usually covered with powdery granules. *Chenopodium Bonus Henricus*, good King Henry, wild spinach, mercury goosefoot, grows abundantly in waste places and by way sides all over Britain. It is a hardy plant, of early growth, flowering in August, and is cultivated in some parts of England, more particularly in Lincolnshire, instead of spinach. The young shoots, after being peeled and boiled, are eaten as asparagus, and possess laxative qualities. The leaves are sometimes applied to wounds, and are used for cleansing old ulcers. *Chenopodium album*, white goosefoot, is perhaps the most common British species of the genus. The whole plant is covered with a white, mealy, unctuous substances which, by age, becomes dry and chaffy. In a young state, it is sometimes boiled in place of greens, and is known by the name of *fat hen* in some parts of Norfolk. *Chenopodium rubrum*, red goosefoot, is another British species, which is found in waste ground, and often in low muddy situations. A considerable quantity of saline matter exists in the juice of this plant, which sometimes crystallizes on the surface of the stem. In exposed situations, the whole plant assumes a red colour. The plant is said to be poisonous to swine. *Chenopodium maritimum*, annual sea-side goosefoot, has been used as a pot-herb, and is burned in order to yield carbonate of soda. *Chenopodium olidum*, or *valvaria*, stinking goosefoot, is found in waste places, and under walls, especially near the sea in many parts of Britain. The whole plant exhales ammonia, or hartshorn, and when recent it has a nauseous taste and a strong offensive smell, resembling putrid salt fish. The odour remains long on the hands after the plant has been touched, in consequence of the greasy pulverulent substance found on the leaves adhering to them. The medical properties of this plant are to be attributed to its fetor. It was formerly used as a powerful antispasmodic, more especially in hysterical affections. It loses its properties by drying, and consequently must always be employed in a recent state. The presence of ammonia, a compound of hydrogen and nitrogen, in this and a few other individuals of the vegetable kingdom, is a circumstance well deserving of attention. *Chenopodium botrys*, or Jerusalem oak, a native of the south of Europe, is filled with a resinous viscous juice, which stains the hands. The leaves when bruised emit a strong odour, and were formerly prescribed in the form of a decoction in some pectoral complaints, such as asthma and catarrh. This species, as well as *Chenopodium ambrosioides*, yield an essential oil, possessing stimulant, tonic, and antispasmodic qualities. The latter species, which is a native of Mexico, has sometimes been called the Mexican tea plant, in consequence of an infusion of it having been formerly used in place of the Chinese beverage. A decoction of the plant has been recommended in palsy. *Chenopodium quinoa*, a native of Chili, is very generally cultivated in Peru, its leaves being eaten as spinach or sorrel, and its seeds as rice. It is also used in the preparation of a kind of beer. Dombey, on his return from Peru, endeavoured to introduce the plant as a culinary vegetable into France, but his attempts were not followed with success. *Chenopodium anthelminticum* yields an essential oil, known in North America by the name of worm-seed oil, which possesses

powerful anthelmintic properties. Similar qualities are attributed to the seeds of this plant.

Of the genus *Atriplex*, or *Orache*, there are upwards of forty species, seven of which are natives of Britain. *Atriplex hortensis*, garden orache or mountain spinach, is a native of Tartary, and has been used as a pot-herb. There are several varieties of the plant, more or less tinged with red and purple. The seeds are emetic, and also cause painful diarrhoea. *Atriplex halimus* grows on the sea coast in the south of Europe, and in this country, its silver coloured foliage adds to the beauty of our shrubberies.

*Spinacia oleracea* furnishes the true garden spinach. There are numerous sorts of spinach, which vary in the shape and size of the leaves, and the greater or less pinkiness of the seeds. The broadest and thickest-leaved varieties are the most esteemed. The seeds are sown in spring and autumn, and grow readily in any kind of soil. The prickly sort are the best for winter crops, and the round for summer. *Basella rubra* and *cordifolia* are two species of Malabar night-shade which are found in the East Indies, Amboyna, and Japan. They bear spinous berries of a very dark red colour, which are used for staining calicoes in India. The leaves are eaten as spinach by the Chinese, and the plants are sometimes cultivated as culinary vegetables in the neighbourhood of Paris.

*Beta vulgaris* yields the culinary root, well known by the name of garden beet, which is so extensively used as a salad or pickle, and from which sugar is sometimes prepared on a large scale. There are several varieties of the plant in cultivation; but the two chief are the red or purple, and the white with red bands. Those most esteemed for salad are the small red and *castelnaudary*, while the green-topped are the best adapted for yielding sugar. The larger and deeper coloured roots are the better. The seeds of the beet are sown in March or April, in deep, well-comminuted soil, and when two or three proper leaves appear, they are thinned in such a way as to allow a square foot of surface for each. By the months of September or October the roots are fit for use, and they are then taken up and preserved in sand. Beet-root, when taken in large quantity, acts as a laxative, but sometimes it proves injurious to the stomach. The juice of the root and leaves causes sneezing. Sugar has been obtained in very large quantities from the beet-root. The plant was formerly extensively cultivated in Germany and France for this purpose, and it is still reared in considerable quantities. During the late wars, when the sugar from the British colonies was not allowed to be exported to France, the beet-root was the only source from which sugar could be procured, and consequently its cultivation became an object of national interest and importance. The usual way in which the sugar is obtained is as follows:—The roots, after being washed and cleaned, are sliced and grated down, and afterwards bruised in successive portions of water, until all the saccharine matter is dissolved. The fluid is then filtered and evaporated, and ultimately purified and crystallised. Besides sugar, the roots contain water, fibrous matter, mucilage, starch, and colouring matter. In general they yield from two to five per cent., of sugar. M. Achard computed that a German square mile, which is equal to sixteen English square miles, would produce beet sufficient to furnish sugar to the whole Prussian dominions.

Sugar, however, cannot be advantageously obtained from this source, inasmuch, as the expense attending its preparation is too great when compared with the quantity produced. A considerable quantity of beet sugar is, nevertheless, annually prepared in France. Beet-roots, when deprived of their juice by pressure and afterwards dried, may be used in place of malt in brewing. The beer made from them is said to be pleasant and wholesome. The leaves of the beet, when reared in a rich, well manured soil, yield a considerable quantity of nitre or saltpetre.

*Beta cicla*, a name corrupted from *Sicula*, meaning Sicilian beet, produces a root, not by any means so large as that of the common beet. The leaves serve as a substitute for spinach, and the young shoots and mid rib of the leaves are eaten like asparagus. The plant grows in great quantity in the south of Germany and in Switzerland. A large variety has been introduced from abroad, under the name of *mangel wurzel*. This variety, on account of the large size of the roots, is now extensively cultivated in this country. It is much used for feeding cattle during the winter. In cultivating this variety, more room is required than in the case of the common beet, on account of the size of the root and leaves. The roots are sometimes applied externally as a poultice to ulcers. The only British species is *Beta maritima*, a sea beet which, when boiled, is esteemed a wholesome article of food.

Most of the species of *Salicornia*, another genus of this order, abound on the shores of the Mediterranean, and two of them are natives of Britain. *Salicornia herbacea*, the most common British species, is gathered when in flower, and pickled in salt and vinegar like samphire. The whole plant has a saltish taste, and is eagerly eaten by cattle. *Salsola kali*, or prickly salt-wort, is common on the sandy sea coasts of Britain, and has also been used as a pickle. *Salsola fruticosa*, found on the shores of the southern counties of England, deserves a place in gardens as being a hardy evergreen. The *Salicornias*, *Salsolas*, various species of *Atriplex* and *Anabasis*, as well as the *Chenopodiums* found in salt marshes, as well as several other plants belonging to the same natural family, growing in the south of Europe and north of Africa, yield, when burnt, a vast quantity of the substance called *barilla*, an impure carbonate of soda, which is used in making glass and soap. The English name of *glasswort*, applied to *Salicornia*, is derived from this circumstance. *Salsola soda* is cultivated extensively in Languedoc and Spain, for the preparation of barilla, which is usually exported to Italy and Sicily, but it is looked upon as inferior to the *Salsola sativa* which grows on the Spanish shores of the Mediterranean. The latter species supplies the Alicante or Spanish barilla, which is the best that is consumed in Europe.

The production of soda depends solely on the proximity of the plants to the sea, for it is from this great saline reservoir that the alkaline matter is derived. The same plants, when cultivated in the interior and far from the shore, yield totally different products.

The maritime plants employed in the preparation of soda, differ in different countries, and the quantity of alkali obtained is very various. Thus, while some kinds of barilla yield from twenty-five to thirty per cent. of alkali, others only yield twelve or fifteen; and the coarser substance called *kelp*, obtained

from sea weeds, yields only two or three per cent.

The preparation of barilla is carried on to a great extent on the shores of the Mediterranean, and there the seeds of various maritime *Chenopodeæ*, are regularly sown in places near the sea. In the month of September, when the plants have attained sufficient maturity, they are pulled up by the roots and exposed to dry, so that the seeds may be collected; they are then gathered into heaps, and afterwards burned in holes made in the ground, or in ovens constructed for the purpose; the ashes are constantly stirred, while hot, with long poles, and a hard mass ultimately remains, which, when broken into pieces, constitutes the barilla of commerce. The best sort of Spanish barilla has a dark bluish colour, is very heavy and dry, has no offensive smell, and is covered externally with numerous small depressions. That which is mixed with small stones, and gives out a disagreeable smell in solution, and is deliquescent, ought to be rejected as bad. From barilla, carbonate of soda is easily obtained by lixiviation in boiling water, and subsequent evaporation.

Carbonate of soda is of great use in the arts and manufactures, more especially in the formation of glass, and in the preparation of various kinds of soap. Glass is formed by mixing soda or potass with sand in certain proportions, and exposing the mixture to a strong heat, until the materials are fused; it is then moulded into different forms under the name of flint, crown, plate, and bottle glass. Bottle glass is the coarsest kind, and is made from river sand, which contains iron and other impurities, and the common impure alkali. Crown glass, for windows, requires fine sand, free from iron, and a pure alkali; white plate glass, for mirrors, is made from the purest materials. To the glass commonly called flint glass, some oxide of lead and manganese is added. Soap is prepared by mixing different kinds of oil, in a greater or less degree of purity, with carbonate of potass or soda; the former alkali being employed in the preparation of soft, and the latter in the formation of hard soap. The soap ordered in medicine for internal use, is formed from the finest olive oil and pure carbonate of soda.

The purest barilla, though well fitted for ordinary manufactures, does not serve for chemical purposes, on account of the mixture of the sulphates and muriates of potass and soda. A carbonate of soda, considerably purer, is easily got by exposing sulphate of soda, or Glauber's salt, with saw-dust and lime, to the action of a reverberatory furnace, and afterwards lixiviating and crystallising.

*Blitum* is another genus of this order, furnishing several species, one of which *Blitum capitatum*, berry-headed strawberry blite, is a native of Austria. In this species, after the flowers are faded, the heads swell to the size of wood-strawberries, and when ripe, have the same colour and appearance. They are succulent and stain the hands, and were formerly used by cooks for colouring puddings. Another genus *Campylosoma*, receives its name from emitting a smell of camphor.

From the above account of the *Chenopodeæ*, it will be seen that the plants of this order, although they contribute little to the ornament of our gardens, are still of considerable importance and interest, when we consider the useful purposes to which they are applied. Many of them are among the most common weeds of

the countries in which they grow, and yet, when properly used, they contribute, in no small degree, to the comforts, and even the luxuries of life.

CHENOPODIUM (Linnaeus), vide GOOSEFOOT.

CHERIMOYER is the *Anona cherimolia* of Mikan, an excellent South American fruit tree. A majority of the anonas yield useful and pleasant fruit, but the cherimoyer is the best of all.

CHERMES (Linnaeus). Under this generic name were designated, in the Linnæan system of Entomology, numerous minute insects, allied to the aphides, from which they are distinguished by the antennæ having ten or eleven joints, and by their powers of leaping. These insects, of which there are various species, have been termed by the French Entomologists false aphides. They subsist upon plants. Geoffroy, however, considering that the term *chermes* had been improperly applied by Linnaeus, gave to these insects the name of *Psylla*, derived from the Greek, and having reference to their saltatorial powers, whilst he employed the name of *chermes*, in its more legitimate sense, to denominate some of the Linnæan species of *Coccus*, which had been used as dyes; the names *Chermes*, *Kermes*, or *Althermes*, having been given by the Arabians and Persians to the *Coccus ilicis* of Linnaeus, which is found abundantly upon the small evergreen oak, *Quercus coccifera*, growing in the south of France and other parts of the world, and which has been employed to impart a blood red or crimson dye to cloth from the earliest ages, having been known to the Phœnicians before the time of Moses, under the name of *Tola* or *Thola*, and to the Greeks under that of *Coccus*. It was with this that the Greeks and Romans produced their crimson, and from the same source the unfading reds of the tapestry of the Low Countries were derived. With a solution of alum it produces a blood red, but when mixed with the solution of tin, as brilliant a scarlet is obtained as that derived from cochineal. As, however, ten or twelve pounds of *chermes* contain only as much colouring matter as one of cochineal, the latter, at its ordinary price, is cheapest. Introduction to Entomology, vol. i. page 321.

As Entomologists, in general, have adopted Geoffroy's name of *Psylla* for the insects first above mentioned, and as the majority of them have not thought it necessary to divide the Linnæan genus *Coccus*, as Geoffroy has done, we shall defer any further observations upon the *Chermes* of the latter author, until our articles upon *Coccus* and *Cochineal*.

CHERRY. The cherry is one of our most common, as well as most beautiful garden and orchard fruits. Like other wild genera, it has been wonderfully improved by art, and many excellent varieties have been obtained by the art of manual impregnation, and not a few by accident. In its wild state the cherry is a lofty tree, producing valuable timber, useful to the cabinet-maker, turner, and other workers in wood. The timber is also durable; a gate-post made of the heart of a cherry-tree, lasts as long as one made of the heart of oak. All the improved varieties of this tree cultivated in gardens, are more or less dwarfed, and changed in their manner of growth, as well as in the manner of bearing their fruit.

A deep sandy loam appears to be the most genial soil for the cherry; and some of the sorts, as the Kentish, for instance, grows and bears well in what may be called pure sand.

The improved varieties cannot be raised from their seed; for though these varieties were at first originated from accidental or artificial impregnation, yet the effect of the strange pollen appears to be confined to the progeny following immediately after impregnation, because the seeds of the next generation, that is, seedlings from the improved variety, retain no feature of the improvement, but go back to their original wild character. It seems therefore, in this, as in other cases of the same kind, that the mixture or influence of strange pollen, effects a change in the habit generally, in the enlargement of the leaves and pulpy covering of the stone, and in the organisation of the kernel belonging to the flower impregnated, but that this influence on the kernel is not permanent, and ceases after the first year.

But although these improvements cannot be perpetuated by seeds, they are readily and purely continued by the common practices of grafting or budding on their own stocks, or rather upon stocks raised from the stones of wild cherries.

Cherry trees do not all bear flowers and fruit in the same manner; the morella bears on the last year's young shoots; and the may-duke and most of the others bear on shoots, also produced in the past year, but from the older wood, and so short that they are called spurs. This difference in the manner of bearing indicates the manner in which the trees should be pruned and trained. The morella for instance, is pruned and trained like the peach tree, because they both bear fruit in the same manner, namely, on the young shoots of the previous year. The other sorts, as the may-duke, when planted against walls, or as espaliers, are trained in the fan manner, or horizontally, or in any other way, that the strength or vigour of the tree may indicate. A weakly growing tree should be trained erect, that is, have its branches laid in as nearly upright as possible; while a strong grower should be laid horizontally, or drooping, in order to cause fruitfulness. As low standards in gardens, or high standards in orchards, cherry trees of all sorts generally do well if the soil be suitable. Such trees seldom want pruning, except to cut out dead wood, or over-crowded branches which press on each other. Old worn out standards are often profitably renovated, by having their largest branches cut back.

In orchards attached to farm homesteads, we often see cherry trees in great perfection, and yielding a considerable revenue to the owner. The cherry orchards of Kent, and other counties near the metropolis, are famous for the income derived from them. The farmers manage their trees well; and one part of their practice deserves imitation. They plant strong healthy stocks in the place where the tree is intended to stand; and when these are well established, graft or bud them with the desired sort. This is a good practice, and suitable for all other orchard fruit trees, as well as cherries. Grafting is preferable for sooner obtaining a spreading head, and for rendering it less liable to be blown off by the wind. Budding, however, is not so likely to gum at the place of insertion; and ultimately forms a perfect union with the stock, if care be taken to give the first shoot or shoots the necessary support during the second and third year after working.

Cherries are much preyed on by birds, and to preserve them requires no little care. In cherry orchards a keeper must be constantly, early and late, on the

alert, to frighten away the thieves. In gardens, nets are the best defence; but they can only be used conveniently against walls, or over espaliers or low standards. The tree is liable to suffer from the attack of insects. The aphid often settle in great numbers on the points of the shoots, and not only prevent a healthy growth, but disfigure the fruit by the honey-dew which these insects emit. A fumigation with tobacco smoke a fortnight or three weeks before the fruit ripens, will kill or drive away the insects. For this purpose a thin canvas cloth of sufficient size to cover a tree, in the open air, is requisite; but it is better to prevent the insects settling by repeated and forcible watering, than have to drive them by any such nauseous application as either tobacco or brimstone.

The delicate blossoms of the cherry, and all other early-flowering fruit trees, are liable to be withered and destroyed by dry winds and hot sunshine, as much as they are by frost. This is the reason that if they chance to blow in cloudy weather, or during a wet time, more abundant crops follow, than when the blooming takes place under bright sunshine. For this reason also, it is, that morella and other sorts, as well as some kinds of plums, are more prolific on a north than on a south wall or aspect, merely because the tender pistil and stamens of the flowers are scorched before they have performed their respective functions. This shows that shading by day is quite as necessary as covering from the frosts of night. This fruit tree is also subject to be enfeebled and barren, from its over-abundant flowering; a circumstance which, if it happens when the weather is favourable for the flowers, a great load of small worthless fruit is the consequence; and if the weather be hot and bright, every flower will be withered, because of weakness caused by their superabundance. In this case thinning the buds or flowers before they blow, or rather as soon as they burst from the bud, will prevent exhaustion of the tree, invigorate the reserved flowers, and ensure a regular crop.

The may-duke forces well; but they require a house built on purpose. Dwarf plants three or four years from the bud, and standards of the same age, should be planted to fill the house from front to back. Gentle forcing, very gradually increased, with a constantly moist atmosphere within the house, are the circumstances indispensable for cherries forced to yield their beautiful fruit in March and April.

There are many varieties of the cherry now in cultivation, of which for gardens the following are particularly suitable, viz. may-duke, graffion, blackheart, whiteheart, biggaroon, Kensington duke, Knight's blackheart, and morella. For farm orchards the Kentish and caroon are the most certain bearers; the last growing to a fine stately tree.

**CHERSYDRUS.** A genus of true serpents found in Java, and the other isles of the Sunda group. Some writers have confounded it with *Acrochordus*, which is not a poisonous serpent, and has the scales with small crests, and interspersed with warty tubercles. This species, on the other hand, has the scales all over the head and body small and flat, and ensiform in appearance. This genus inhabits the bottoms of rivers in the countries above named, and is described as being very venomous. The chief difference between it and the other water serpents which are poisonous, consists in the smallness of the scales on its head. It

has not been positively ascertained whether this species is ovoviparous, that is, whether it hatches its eggs internally, and brings forth the young alive; but the analogy renders this probable, as that is the case with all the venomous serpents of whose mode of production we have any knowledge. The habits of the aquatic ones are not, however, so easily studied as those of the land, and even they are but little known.

CHERVIL is the *Cherophyllum sativum* of botanists. It is a native of Britain, and cultivated as a salad or pot-herb. It being an annual, the seeds are sown in the spring, and at several different times afterwards, where a supply of the tender leaves are required. It belongs to the natural order *Umbelliferae*.

CHESTNUT is the *Castanea vesca* of Thouars, and the *Fagus castanea* of Linnaeus. There are four species, and several varieties of this fine useful genus in cultivation. As a timber tree it is only equalled by the oak; it being equally picturesque in habit, and as durable when converted to the purposes of the builder. For coppice wood it is unrivalled, yielding as quick a return as any other kind of tree whatever.

It is to be regretted that our early planters—that is, all those who were prompted by the immortal Evelyn to improve and adorn their estates and country seats by planting forest trees, did unaccountably neglect the sweet chestnut. It could not be from ignorance of the value of the timber, because it had always been previously used in the construction of the roofs of public buildings; nor could it be from fear that the trees would not succeed in these kingdoms, as, if not the largest, certainly the oldest tree in England was a chestnut, then and we believe now growing in Gloucestershire, a tree which was called “the great chestnut” in the reign of King John. Nor was the propagation difficult. Seeds in any quantity could have been had from Spain and other parts of the continent at any time; and no seeds rise more readily, or grow away more vigorously, than chestnuts, provided mice, squirrels, and jays, can be kept from devouring them while in the seed-bed. Sowed in a bed of any light soil in the month of March, not too closely together, and covered with about an inch and a half, or two inches of soil, they soon make their appearance, and where they may stand till large enough to be transplanted into nursery rows in an open quarter.

The sweet chestnut requires a kind of training in the nursery, much more than other forest trees do. They rarely rise with a single stem; but beside the principal stem, which is always the most central, four or five others rise from the collet, and were they suffered to remain, would disfigure the tree, if intended to grow as a forest, or for open grove planting. These supernumerary stems are, therefore, pruned close off when first transplanted from the seed-bed; and, while standing in nursery rows, all such side shoots from the lower part of the stem, must be pruned off.

This character and manner of growth of the chestnut seedlings, and which requires the attention of the nurseryman to correct in the first stages of their growth when intended for timber, is the very property for which this tree is so suitable for underwood. Here the greater number of stems which rise at once from the root, not only increase the value of the produce, but improve the form of the poles, by inducing a more upright and straight growth.

From the circumstance of many of the principal timbers in the roofs of our cathedrals being found to be chestnut, it has been surmised by several writers, that this tree was once plentiful and of great size in this country. The only argument against the probability of this idea is, the present scarcity of this tree in our parks and natural forests; for, if they were at any former period natives, why should this kind of tree have so suddenly disappeared. The greater probability is, that when a cathedral was about to be built, all Christendom was called on to assist, especially when the Pope could issue imperative commands on such occasions. And it is most likely, that the beams and rafters of Westminster and other cathedrals, were from the forests of Spain and Italy.

As a fruit tree, the chestnut is of little value in England, it being only in very favourable seasons that the nuts come to perfection. As an ornamental and timber tree, however, it deserves the first notice of the planter; and as it has been pretty extensively planted within these last four-score years, another generation, perhaps, may see chestnut timber as plentiful as the best oak is at the present time.

Sweet chestnut underwood, judiciously planted on light loamy soil, and carefully managed, proves a profitable possession; the produce being usually fit to cut every eight or ten years, and sells at high prices. Hop growers prefer chestnut poles, as well for their regular form as durability; and the stools yield great numbers of stakes and headers for fencing.

CHICK PEA is the *Cicer arietinum* of Tournefort. This plant is cultivated in the south of Europe, where it is indigenous, and is an article of diet among the poor, but is chiefly used for feeding poultry.

CHIGOE, or, as the English residents in the West Indies have corrupted the name, *Jigger*. A species of insect belonging to the family of fleas, *Pulicidae*, but considered by Latreille as probably forming a distinct genus. The names *Nigua*, *Tungua*, and *Pique*, have also been applied to this insect, but Latreille has considered that the first and third belong to the *Acarus Americanus*, whilst he gives the *Chigoe* as another species of *Acarus*. Mr. Mac Leay, however, who, from his residence at the Havannah, must be considered a more competent authority, states that the Spanish name for the troublesome *Pulex penetrans* is *Nigua*, and the British West India name *Chigoe* or *Jigger*. The habits of this insect are very different from those of the common flea. According to Stedman it gets in between the skin and the flesh without being felt, generally under the nails of the toes, where, while it feeds, it keeps growing till it (or rather its habitation) becomes of the size of a pea, causing no further pain than a disagreeable itching. It will, however, attack any exposed part of the body; indeed an instance has been recorded where it got into the hand. In process of time its operation appears in the form of a small bladder, in which are deposited thousands of eggs or nits, and which, if it breaks, produce so many young chigoes, which in the course of time create running ulcers, often of very dangerous consequence to the patient, so that at times the soles of the feet are even obliged to be cut away before the patient can recover, and some men have lost their limbs by amputation, nay, even their lives, by having neglected to eradicate these abominable vermin. The moment, therefore, that a redness and itching more than usual are perceived, it is time to extract the chigoe which produces them. This is done with a sharp pointed

needle, taking care not to occasion unnecessary pain, and to prevent the chigoe from breaking in the wound. The female slaves are often employed to extract these pests, which they do with uncommon dexterity. Tobacco ashes are put into the orifice, by which in a short time the wound is healed. Here, however, as in the attacks of most other tormenting insects, we find that cleanliness is the best preservative, persons who take care to wash their feet often, being but little subject to annoyance. It is likewise found that rubbing the feet over with bruised tobacco leaves is a preventive against them. Great uncertainty prevailed as to the real nature of this insect until Swartz investigated its history, and published a short paper upon it in the Stockholm Transactions, proving that it belongs to the flea family. He has, however, represented it with a long prorected proboscis.

**CHILOCHLOA** (Beauvois). This is a genus of grasses, formerly known and included under the genus *Phleum*. They are mostly annuals, and of no value as agricultural plants.

**CHILOGLOTTIS** (R. Brown). A curious tuberos rooted orchideous plant from New Holland, introduced into our collections about 1823. This is a pretty hardy plant, and is usually kept in a frame, planted in turfy moor-earth, or "in the open border if care be taken to defend it from frost."—*Sweet*.

**CHILOGNATHA** (Latreille, MacLeay). An order of wingless insects, corresponding with the apterous genus *Iulus* of Linnæus, and distinguished by having the body long, crustaceous, and often cylindric, and the antennæ seven jointed, and forming, in the system of Latreille, one of the two families of which the order *Myriapoda* is composed, the other being formed of the *Centipedes*, *Chilopoda*, or the Linnæan genus *Scolopendra*. These two groups have many characters in common; they are equally possessed of a very great number of legs; the abdominal are not distinguished from the thoracic segments, as they are in true insects. The body, destitute of wings, is composed of an extensive series of segments, of equal size, and bearing, with the exception of the anterior, two pairs of legs, as noticed in our article on the *Centipedes*. The *Myriapoda* somewhat resemble small serpents or nereides, having the legs fixed close together throughout the whole length of the body. The antennæ are two in number; the eyes are composed of an union of ocelli, and if, in some species, these organs offer a faceted cornea, each of the lenses is much larger and more distinct than in the true reticulated eyes of insects; the number of the legs, as well as of the segments of the body, increases with the age of the animal. These animals live, and continue to increase in size for a much greater period of time than insects; and, according to M. Savi, two years are required before the organs of generation become at all apparent. Hence we may conclude, that they approach, in some respects, to the *Crustacea* and *Arachnida*, and in others to the true insects; but, from the consideration of the presence, the form and the direction of the tracheæ, they must be considered rather as belonging to the latter. Mr. MacLeay has united them with the *Anoplura* (lice), *Thysanoura* (sugar lice, &c.), and some apterous vermes into a class, to which he has applied the term *Ametabola*.

In addition to the characters first above mentioned as distinguishing the *Chilognatha*, it may be mentioned that the legs are very short, terminated by a single

claw; two short antennæ; the mandibles are crustaceous, without palpi, and three jointed; but the more distinguishing character of the *Chilognatha* is the position of the sexual organs near the anterior part, and not the extremity of the body; those of the male being placed behind the seventh pair of legs, and those of the female behind those of the second pair. These animals walk but slowly, and with an undulating motion, produced by the progressive action of the numerous legs; the majority of them, when disturbed, roll themselves up into a ball. They feed upon animal and vegetable substances in a state of decay, and lay a very considerable number of eggs in the earth. From these eggs the young are produced, at first without any appendages to the body; eighteen days afterwards, however (in the genus *Iulus*, according to M. Savi of Bologna, who has made these insects the subjects of two valuable memoirs), the skin is cast, when they appear with twenty-two segments, and twenty-six pairs of legs, of which, the first eighteen serve for locomotion; at the second moulting the animal has acquired thirty-six legs, and at the third forty-three; the body being then composed of thirty segments; and in the adult state, the male has thirty-nine, and the female sixty-four.

A very small species of this group attacks the strawberry, another the endive, others are found in moist places, under the bark of trees, &c.

There are numerous species belonging to this order, some of those from South America acquiring a large size—the *Iulus maximus* being seven inches long. Of the British species, Dr. Leach has given a very good Monograph in the Zoological Miscellany.

This order is divided by Latreille, in his last work, into three families:—

1st. The *Onisciformes*, having the body of a crustaceous texture and of an oval-oblong form, without pencil-shaped appendages, and capable of being contracted into a ball; the under side of the body being concave. The number of legs is thirty-two in the males, and thirty-four in the females. This family comprises but a single genus, *Glomeris*, Latreille, the species of which are found under stones, especially in mountainous and woody districts. This group is highly interesting to the naturalist, from the remarkable analogy which it presents to certain crustaceous animals, to which the name of wood lice has been given. Indeed, so strong is the relationship, not only in form, size, and general appearance, but also in habits, that it is no wonder that, by the majority of British naturalists, who have, in general, cared too little for more than the outward appearance of things, the *Glomeris marginatus*, belonging to the ametabolous order *Chilognatha*, should have been regarded as a mere variety of the *Armadillo vulgaris*, belonging to the crustaceous order *Iso-poda*. We trust that better times are dawning on natural history, as a science, in its legitimate sense, in this country. For the purpose of comparison we have represented the two animals above mentioned, from which it will be seen how close is the proximity between the two groups.

2nd. The *Anguiformes* of Latreille, having the body of a crustaceous texture, but of a long and narrow form, and unprovided with pencil-shaped appendages. Here belong the genera *Iulus* and *Craspedosoma*, having the eyes distinct, and *Polydesmus* in which they are obsolete.

3rd. The *Penicillata* of Latreille, having the body soft, oblong, and furnished behind with small pencil-

like brushes. The legs are twenty-four in number. The genus *Polyxenus*, Latreille, belongs to this family. The type is found in profusion beneath the bark of trees.

1, *Glomeris marginatus*. 2, *Armadillo vulgaris*.

**CHILOPODA** (Latreille; *Syngnatha*, Leach). An order of wingless insects, corresponding with the Linnean genus *Scolopendra*, and distinguished by having the body of a leathery-like texture, and depressed, and the antennæ composed of fourteen or more joints. See CENTIPEDES and CHILLOGNATHA. Having, in the former of these articles, given an account of the structure and habits of the animals of which this order is composed, it only remains for us, in this place, to give a short sketch of their classification.

Dr. Leach, in the Supplement to the Encyclopædia Britannica, has divided this order into three families.

1st, The *Cermatiidæ* (*Inaequipedes* of Latreille's Cours d'Entomologie), having the body proportionably short, with the upper surface protected by eight plates, and with the under divided into fifteen semi-segments, each bearing a pair of legs, terminated by a very long and multi-articulate tarsus. This family, which is composed of the single genus *Cermatia*, is formed of exotic insects, frequently found in houses under beams or joists of the wood work, running with great velocity, and often losing many of its legs when seized.

2nd, The *Scolopendridæ* (*Æquipedes*, Latreille), having the body divided both in its upper and under surface, into an equal number of segments; the legs short and of nearly equal size, the posterior pairs being but little longer than the anterior. Here belong the true *Centipedes*, *Scolopendra*, and the genera *Cryptops* and *Lithobius*, of each of which there are British species.

3rd, The *Geophilidæ* (united with the latter by Latreille), and having a very great number of equal sized legs, the body being narrow and almost filiform, each segment bearing two pairs of legs. Some species are luminous, as the *Geophilus electricus*. Figures of *Geophilus longicornis*, and of *Lithobius forcipatus*, two British species, serving as types of those two families, will be found in our article CENTIPEDES.

**CHIMONANTHUS** (Lindley). A fine ornamental flowering shrub, a native of China and Japan; Linnean class and order *Icosandria Polygynia*; natural order *Rosaceæ*. Generic character: perianth scaled; outer lobes like bractæ, inner lobes resembling petals; corolla, none; stamens inserted in the fleshy throat of the perianthe; exterior ones perfect and small; anthers adnate and two-celled, interior like threads and downy; styles several and filiform. This plant, on its first introduction into Europe, was called *Calycanthus præcox*; afterwards described as *Meratia*, by Loiseleur Deslongchamps, in his Flora Gallica; but finally named by Lindley in the Botanical Register.

This plant is greatly esteemed by the Chinese, not only for its early flowering and fragrance, but for some medical extract obtained from it, and which is particularly available in counteracting the virulence of the small-pox, so much dreaded by that smooth-faced people. It is almost hardy enough to bear the open air in this country; but as it flowers in winter, and as frost tarnishes the blossoms, the best way to see it in beauty, is to give it a place in the conservatory, or against a south wall in the flower garden. Mr. Sweet states that there are three varieties or species in the London collections, all of which thrive in any kind of garden soil. The plants are usually raised from layers, or by young cuttings planted in sand under a glass, and placed in hothed heat. Seeds sometimes ripen in this country, whence seedlings are easily raised.

**CHINCHILLIDÆ**. The chinchilla family, an exceedingly interesting, and, in so far as individuals are concerned, a remarkably numerous group of rodentia, or gnawing animals, inhabiting the southern parts chiefly of South America. The fur of one species (*lanigera*), has been known and highly prized for a considerable number of years; but it is not very long since much was known in Europe, either of the animals themselves, or even of the country of which they were natives.

It has now, however, been tolerably well ascertained that there are three distinct species, if, indeed, they ought not rather to be, as they sometimes have been considered as separate genera.

They all belong to the herbivorous division of gnawing animals, and their teeth are adapted for bruising the hard and dry vegetation upon which, from the peculiarity of their native regions, they are sometimes obliged to subsist, as well as on the more succulent leaves which they can procure in the season of growth. They are all gentle and inoffensive animals, spending great part of their time in their burrows under ground, though in many parts of the plains their burrows are so very numerous, that the horses of travellers and hunters are in constant danger of stepping into them, and throwing their riders, and fracturing their legs.

At one time they were confounded with the hamsters (*cricetus*), to which they have a good many points of resemblance; but still, in their appearance, their structure, and their locality, they are fully entitled to rank as a distinct family, and a family which gave no small portion of its original character to the zoology of the district in which they are found. Nor is it a little remarkable, that two portions of the world, which, from the geographical antipodes to each other, at least, as nearly as any two portions of land of considerable extent should have a remarkable coincidence in their mammalia, even although in climate, as well as in local position, they differ very much. Siberia, especially the southern parts of the steppes, which lie near the bases of the Altaian mountains, have, in many respects, a structural resemblance to the pampas or plains which lie between the Rio-de-la-Plata, and the southern Andes. Both are flat, and composed in great part of sand. Both are, in many places, burnt up at one season of the year, and covered with rich herbage at another, and both are but thinly inhabited, in consequence of the paucity of their productions as serviceable to man; but both contain an immense number of herbivorous rodentia. In respect of its fur animals, Siberia is, indeed, a sort

of union of the two ends of the American continent; the woods furnishing animals not very dissimilar to those which are found, in such vast numbers, to the north westward of Canada, while the open and arid-places present us with those of Paraguay, or rather with animals resembling these in their general habits. But still there is a great difference in the climates of the two places; for, though the southern Andes, on the parallel alluded to, are subjected to more violent storms than any part of Siberia, the plains have a much greater uniformity of temperature, so much so, that up to the very southern extremity of the American continent, vegetation retains a tropical character. We might, therefore, be prepared to expect a considerable difference between the appearance and covering of the animals which perform the same part in the economy of nature in each of the two. And, accordingly, we find the fur upon the American animals much more delicate, and not nearly so well adapted for throwing off snow as that of the Siberians. They are also more gentle animals; and they probably more habitually burrow in the ground.

The characters of the chinchillidæ are,—two simple incisive teeth in each jaw, and four grinders in each side of both jaws. The grinders, as is general in all the herbivorous part of the order, have no roots, and are not produced in the substance of the gum, but grow, adhering to its surface; and, as is the case with all teeth that grow in this manner, they continue growing during the whole life of the animal. Animals of this tribe have all to subsist on very hard food at some season or other; and therefore, this constant growth of the teeth is a very wise provision for them. The teeth of the family under consideration have parallel plates of enamel and osseous matter; and their bruising crowns act directly against each other.

There are three genera, *Lagotomus*, on the east side of the Andes; *Chinchilla*, on the lower slopes of the mountains, and *Lagotis* on the western side. The first genus gets its name of "hairy mouth," from its remarkably produced whiskers; the name of the second is a country name; and the third is called "hairy ears," from the large size of these appendages. The first and third are indiscriminately called *Viscacha*; and thus, it is necessary, not to confound the one with other. The first, or eastern one being best known, may be considered as the true *Viscacha*; and, perhaps, for the sake of popular distinction, it may be as well to apply the epithet *Peruvian* to the other.

The *Viscacha* (*Lagotomus trichodactylus*) is about the size of a rabbit. It has also a good deal of the manners of that animal, only it is much less timid, and the vast production of grey fur on the cheeks gives it a very grave appearance. The grinders have two oblique lamellæ in the first three, and three in the last one, at least in the upper jaw: three toes on the hind feet, and four on the fore; thumbs always wanting; nails on the toes, nearly straight, and very strong; the ears and tail of mean size. The colour of this species is grey, of different shades, arising from the points of the individual fibres being of a different colour from the greater part of the length. The skin is of no great value as fur, and the flesh is described as having rather a rank and musky flavour. It is, we believe, sometimes eaten by the Indians, though there is little temptation in a country where wild cattle are to be had for the labour of catching them. The fibres of the covering of this animal are individually

long, but they are coarse, and so few in number, that they do not conceal the skin, so that they are by no means ornamental; and this inutility of the animal, both as food and as clothing, leaves it at peace to multiply to that vast abundance in which it is found in the plains above mentioned.

*Chinchilla* (*Chinchilla lanigera*). This species is as remarkable for the delicate texture and closeness of its fur as the former is for the opposite qualities; and of the same individual the colour is about uniform all over the body, which renders it very available to the furrier, who can thus obtain an article of large size without any appearance of patching. The fur is so well known, that any description of it would be superfluous; but we may remark, that, notwithstanding its extreme softness, it adheres very firmly to the skin. Some varieties of the chinchilla have been mentioned, but they are at any rate nothing but differences, and very slight differences, of colour; and it is very probable that, as has been the case with some other animals, a clean skin and a dirty one have been described as different species.

The leading characteristics of this animal are: teeth same in number as in the former species, but they have three oblique ridges in each, and the front grinders in the upper jaw are divided into two lobes; the fore-feet have the thumb complete, and consequently five toes; the hind feet have only four toes, and a rudimental thumb. The ears are very long, and the tail partakes of a similar character. It does not appear that this animal is so constantly found burrowing as the viscacha, for it is frequently found lurking in holes of the rocks. It extends geographically over great part of the neighbourhood of the Andes, both in Chile and in Peru, and its numbers are very abundant. It is a much smaller animal than the viscacha, and every way much more delicate in its appearance; but the fineness and closeness of its fur enable it to endure the cold much better.

*Lagotis* (*Lagotis Cuvieri*) has still the same number and general structure of teeth, but the grinders have three single oblique lamellæ in each. There are four toes on all the feet, the thumb being deficient. The nails are small, and a little knife-shaped. The tail is long, and the ears very long.

In its size, and also in the general shape of its body, this animal very much resembles a rabbit, but the tail, which is equal to the whole body, exclusive of the head, gives it a very different appearance. It is a jumping animal, and has its hind legs of nearly twice the length of the fore ones. The bristly hairs of its whiskers are quite black, very numerous, very closely set, and some of them more than half a foot long. The ears are about three inches long, one inch in breadth, and cut square over at the tips; they are almost entirely destitute of fur. The hair on the fore feet is long and bristly, and almost entirely conceals the claws. The inner toe on the fore feet is flattened, curved inwards, and has its inner margin beset with stiff bristles, which have nearly the consistency of a small comb. This last circumstance is not, however, peculiar to it, for it occurs also in the chinchilla.

The hair of this animal is very soft and downy, of considerable length, and beautiful in appearance, but it adheres so slightly to the skin as to render it of no value to the furrier. The base of the hairs is dusky, and about a quarter of an inch at the tip, of a dull

white, with more or less of a brownish tinge. Besides this very soft fur, there are bristly hairs scattered thinly over the body of the animal, which are of a black colour. This animal is found chiefly upon the

margins upon those dry and sterile plains which lie between the Andes and the Pacific, intermediate between Chile and Peru, though it is met with to a considerable extent over both these countries. From the tenderness of its covering, it is not, though a stronger and larger animal, so able to bear the severity of winter in the Andes as the Chinchilla, though it is not so decidedly an animal of the plains as the viscacha of Paraguay. It is possible that both species may occur both in the east and the west of the mountains, though, for great part of the ridge, the summits are so elevated, the weather upon them so severe, and the passes so difficult, that they form nearly as impassable a barrier to all animals that cannot fly as the same extent of the ocean itself. It is highly probable that there are more species, or, at all events, varieties of this family, at one place or another of the country in which the known ones occur; but on this, as on very many other points in the natural history of South America, our information is still very imperfect, though it is making a very rapid progress, especially of late years, and since the Spanish colonies threw off the yoke of the mother country.

**CHINESE ROSE** is the *Hibiscus rosa Sinensis* of Linnæus. It is in no way connected with the *Rosa indica*, which is a species of the common European rose; but it is so called because the form, colour, and number of the flowers of the *Hibiscus*, when seen at a distance, resemble, in their native country, the rose tree of England. This *hibiscus* is indeed a highly ornamental plant, and as the flowers are of different tints, even on the same plant, they are great favourites of the Chinese, as well as of European residents in India, who plant them in the shrubberies round their houses. They strike root readily from cuttings.

**CHIOCOCCA** (Willdenow). A genus of West Indian shrubs lately introduced into our collections. Linnæan class and order, *Pentandria Monogynia*; natural order, *Rubiaceæ*. Generic character: calyx pitcher-shaped, five-toothed; corolla funnel-shaped, throat bearded, stamens included; stigma entire; berry pulpy and two-seeded. This is called the snowberry-bush, from the colour of the fruit. It is easily propagated by cuttings treated in the ordinary manner.

**CHIONANTHUS** (Linnæus). Fine ornamental North American trees and shrubs, common in our pleasure-grounds. Linnæan class and order, *Diandria Monogynia*; natural order, *Oleaceæ*. Generic character: calyx four-parted, persisting; corolla tube short, limb cut into many linear divisions; stamens have short

filaments seated within the tube; anthers heart-shaped and erect; style short; stigma three-cleft; drupe one-seeded. This handsome plant is called the fringe-tree, from the elegant form and position of its flowers. The leaves are also large and showy. Plants are raised from imported seeds, or propagated by grafting on the common ash.

**CHIRONECTES**. A genus of spinous-finned fishes belonging to Cuvier's thirteenth family, or those which have the pectoral fins pedunculated. They have the carpal or wrist-bone so much produced as to form a peduncle to the fin, which has some slight resemblance to an arm, to which the fin itself serves as a sort of hand. The present genus bears some resemblance to the frog fishes, or anglers, which are remarkable for their grotesque form. They have prominent appendages to the head, which form a crest, sometimes terminating in a sort of membrane, and at other times in a sort of fin. Their head and body are compressed; their mouth opens vertically; their gill-flaps consist of four rays, and there is no gill-opening, but a small hole behind the dorsal fin. They have four gills. Their dorsal fin occupies the whole length of the back. They are furnished with a very large swimming bladder. Their intestinal canals are of mean length and without any cæca; but their stomachs are very large, so that they can, upon occasion, puff themselves up like a balloon.

They are found chiefly in the muddy bays and estuaries of tropical seas, and, contrary to the habits of most fish, they do not retreat with the tide. There are, indeed, few fishes which can bear the absence of water longer; for they may be kept on land for two or three days, with little falling off of their activity. They obtain the name of frog-fishes, from their hopping along the surface of the mud at low water, very much after the manner of these reptiles; and in some of the bays on the north coast of Australia, where the violent rains wash the soil into the sea, they may be observed at low water hopping about in great numbers. Their pectoral fins, which have a great deal of muscular action, are made use of as feet on their march over the mud; and though they do not use these alternately in stepping, they can spring to the height of several feet, and the distance of a yard or two. This curious mode of marching is by no means an idle sport with them; for immense numbers of insects hover over the mud in those hot climates, and these fishes spring up and make prize of them. There are a considerable number of species, which are chiefly distinguished by the different appendages to the skin, some of which are spines, and capable of inflicting rather unpleasant wounds, though in this respect they are not so formidable as some of the allied genera. They are by no means handsome fishes, nor does it appear that they are eaten even by the rudest people.

**CHIRONECTUS**. A genus of marsupial animals, of aquatic habits, and but for the fact of its being marsupial, while the otters are not, it bears a considerable resemblance to the otter, and is called the little otter by European settlers in those parts of the world where it is found.

The characters are:—six incisive teeth in the upper jaw, and eight in the under; two canines in each; the number of grinders indefinite; the muzzle pointed; the eyes directed laterally; the ears naked, and membranous; five toes on all the feet, of which the hind ones only are webbed; no nail on the thumb of the

hind feet, but crooked claws on all the others; plantigrade in walking; tail cylindrical, covered with scales, and prehensile. There is only one species which is often described as the palmated or web-footed opossum. This species is *CHIRONECTUS YAPAK*, the Yapack. It is found in the rivers of Guiana, and the adjoining parts of South America. It is a small animal, not a foot in length, with a tail of six or seven inches. The form of the head is long and pointed, the muzzle very slender, and the ears large and naked. The tail is naked, with the skin granulated like shagreen leather, and with scaly plates on the under side. The ground colour of the body is greyish yellow; the upper part being marked with blackish brown spots. These spots or patches, which are of large size, give rather an elegant marking to the animal. There is one between the eyes, another on the top of the head, and a third and broader one on the shoulders, which is continued down the front sides of the fore legs to the toes, which are blackish, a fourth of a rounder shape on the middle of the back, and one on the rump, which extends some way down the hind quarters, but not to the legs. Three are united down the back by a narrow dorsal line. The cheeks, and the under part, are marked with pale yellow ash, inclining to white. The general expression of the animal may be judged of by inspection of the annexed figure.

*Chironectus Yapak.*

It is highly probable that, when the banks of the rivers and streams in South America have been examined with sufficient care, there may be found many species; or at all events varieties of these fresh water marsupial animals, occupying the same place in the natural history of that part of the world, as the water rats and water mice occupy with us. Mention has been made of some as having been met with both in Brazil and in Peru, or on the very opposite sides of the continent. Of these, one is said to have been not more than two inches in length. The larger ones, such as the Yapack, feed in part upon small fishes; and it is probable that the smaller ones may live upon water insects; but the country in which they have been seen is so extensive, and has been viewed by scientific eyes at so few points, that all the information which we have, amounts only to a very rude guess at its natural history. America is among the latest additions to the known parts of the world; and, in the southern parts of the mainland and the islands especially the very abundance with which nature has endowed it, has been the means of keeping us in ignor-

ance of its natural history. The gold and silver of the Andes, and the vegetable wealth of the islands and the alluvial parts of the mainland, have so captivated the bad passions of men, that they have not attended to the productions and the working of nature with even half the attention which has been bestowed upon the most sterile parts of the globe.

**CHIRONEMUS.** A genus of spinous-finned fishes belonging to the perch family. They have seven rays, and are without the crooked teeth which characterise perches. There is only one known species, a native of the Australian seas.

**CHIRONIA** (Linnaeus). A beautiful genus of undershrubs, natives of the Cape of Good Hope. Linnæan class and order, *Pentandria Monogynia*; natural order, *Gentianææ*. Generic character: calyx in five divisions; corolla open bell-shaped, limb five-cleft; stamens bearing oblong erect anthers; stigma round; capsule united to the calyx. The chironias should be in every greenhouse, as they are free flowerers, and bear purple, or red or white blossoms. They are easily propagated by cuttings, and require to be often renewed by this means, as old plants become irregular in growth, and unsightly.

**CHIRONOMUS** (Meigen). A genus of dipterous insects belonging to the great family *Tipulidæ*, and to the sub-family *Culiciformes* of Latreille. The insects of which this very numerous genus is composed are of small size, and are often, but inappropriately, termed gnats, that name being, as it seems to us, more strictly applicable to the *Culicidæ*, from whose stings, or rather bites, we have so often cause of inquietude and alarm. We would apply to the present and other harmless insects belonging to the former family the name of *Midges*. Generally these insects are distinguished by the beautiful antennæ of the males, which are thirteen-jointed, and form a complete feather, being entirely enveloped in a pencil of hairs reaching to the tip; those of the females are clothed with a few short hairs, and only six-jointed, the terminal joint being very long. The abdomen is long, slender, and hairy, the legs long and slender, the anterior tarsi being often very long, and seldom employed in walking, and the wings are laid parallel upon the back during repose.

It is these insects which are so often observed in fine summer evenings hovering in great swarms over moist situations, and alternately rising and falling with a motion somewhat like that of the May-flies, *Ephemera*. In the Linnæan system the midges formed portion of the genus *Tipula*, which from its great extent has been separated by modern authors into numerous generic subdivisions; they resemble the true gnats, but the proboscis which in the latter is so direful an organ is here nearly rudimental. Like the gnats they reside in the larva state in water, and are provided with various organs for respiration, which they continually apply to the surface in order to procure a sufficient supply of air. The larva of the common *C. plumosus* has been observed by De Geer and others. It is long, slender, worm-like, and may constantly be seen in stagnant water and ditches, being of a red colour, whence it has obtained the name of the blood-worm, its body is articulated, and its tail is furnished with several short fin-like appendages for respiration. These larvæ form long cylindric tubes in the banks, in which for the most part they reside, and in which they change to pupæ. An anecdote is recorded respecting these blood-

worms, which is quite sufficient to prove that, in this case at least, even a little knowledge of natural history would not have been a dangerous thing. A medical gentleman having observed these larvæ very numerous in the water of a well, in the neighbourhood of Cork, considered them to be the true origin of the common small thread-worm (*Oxyurus vermicularis*) occasionally found in the human intestines, the former differing only from the latter in colour. Had he, however, but placed some of these worms in water of a temperature equal to the human body, he would soon have discovered that they were not long able to bear the increased heat of their native element.

Reaumur found the larvæ of one of the species in small brown paper-like cases, attached to various leaves which had fallen into the water in the Bois de Boulogne; the cases were of a flattish spindle-shape, somewhat resembling an oblong seed, they were chiefly composed of silk, but Reaumur could not ascertain whether fragments of leaves might not also be employed in their composition. We are unable to decide as to the precise species observed by this author, but from his description it seems nearly akin to the *C. plumosus*. The fore legs are much longer than the others, and generally carried in an elevated position by this insect, so that they might easily be mistaken for antennæ; moreover, they are generally kept in continual motion, now elevated, now depressed, whence the origin of the generic name, signifying a kind of gesticulation with the hands. The pupa has the head and thorax united into an oval mass, with the abdomen long and cylindric; from each side of the thorax arises an elegant apparatus composed of five long finely feathered rays disposed in the form of a star; the tail is also ornamented at its extremity with a fine brush of hair. The fore legs, from their general length, are inclosed in cases which, instead of folding upon the breast in the same way as the shorter hind legs, project from each side of the thorax in a very peculiar manner. Messrs. Kirby and Spence have given a very interesting account of the manner in which the insect, upon arriving at its perfect state, in which it is destined to pass its life in the air, effects its escape from the puparium, or skin of the pupa, the natural element of which is the water. For the extrication of the imago it is necessary that it should remain quietly suspended at the surface, and moreover that the thorax in which the opening for its exit is to be made should be at least level with it, and this is precisely what takes place. By a most singular and beautiful contrivance, not only is the pupa which is specifically heavier than water enabled to suspend itself without motion at the surface, but its thorax which is the heaviest end is kept uppermost. This is effected by the property which the centre of the thorax has of repelling water, hence as soon as the pupa has once forced this part of the body above the surface, the water is seen to retreat from it on all sides, leaving an oval space in the disk which is quite dry, hence the attraction of the air to the dry part of the thorax is sufficient to overbalance the specific gravity of the pupa. If, however, when the pupa is suspended at the surface, a drop of water be let fall upon the dry portion of the thorax, it instantly sinks to the bottom, the thorax which belongs to the heaviest half being the lowest, but if the pupa be again brought to the surface so that the fluid is repelled from its disk, it remains suspended there without effort as before. Just previous to the exclusion of the fly, the

dry part of the thorax is seen to split in the middle. The air enters and forms a brilliant stratum resembling quicksilver between the body of the insect and its puparium, and the former, pushing forth its head and fore legs, like the gnat, rests the latter upon the water, and in a few seconds extricates itself wholly

Larva, pupa, and perfect Chironomus.

from the puparium. A more recent author has endeavoured to throw some doubt upon the mode of solution of the manner in which the suspension is effected, asking in reference to that part of Messrs. Kirby and Spence's statement, which he quotes entire, which relates to the sinking of the insect when a drop of water is let fall upon it. "If so, we may ask what becomes of the power of the thorax to repel water?" We answer that, although the thorax may possess the power to repel the water immediately surrounding it in a quiet and undisturbed state, it does not follow, and indeed it would be absurd to suppose that it possessed a power of repulsion sufficiently strong to resist the increased force of a drop of water let fall upon the heaviest portion of its body, especially at a period when the feeble creature is just as it were upon the point of bursting into life; indeed in support of this opinion, we again find the same author adopting another idea of Messrs. Kirby and Spence, namely, that these midges fly unwetted in a heavy shower of rain, owing to their quickness of vision, since if the drops, bigger than their own bodies, fell upon them, they must be dashed to the ground, although he immediately takes up the idea of repulsion which he had before thrown down, and "unless it may be that the drops glide off their wings as they do off the feathers of a duck."—*Insect Transformations*, 319, 367.

There are nearly a hundred British species of this genus, some of which are remarkable for the elegance of their colouring. Many of them form beautiful subjects for the microscope.

**CHIROTES.** A genus of saurian reptiles, which may be considered as intermediate between the lizards properly so called and those serpents which have rudimental bones of the extremities. From the circumstance of having only two feet, this genus, or we may say, this species, for there is but one, has been rather absurdly called *Bimana*; but as that is the proper distinctive name of the human race in natural history, and as no animal but man is possessed of what can properly be called a hand, the extremities of apes and monkeys being merely grasping feet, it is of course improper to apply the term *bimana* to any species but the human race. This animal is the *Lacerta lumbricoides* of Shaw, but it cannot, strictly speaking, be considered as a lizard, and it has no resemblance whatever to an earth-worm (*lumbricus*) in any one respect, except colour. It is one of those singular animals of which two or three are met with in Mexico, and which have always puzzled the syste-

matists where to place them. The characters are: the head round, blunt at the muzzle, distinguished from the body by a simple fold, and covered with polygonal scales, which are large for the size of the animal but few in number; the nostrils and eyes are not very conspicuous; the jaws are of nearly equal length; the body is long, cylindrical, covered with rather large four-sided scales, which are similar both on the back and the belly, and are verticillate or placed in whorls round the body; there are only two feet which are very near the head, well developed, and each containing five toes with distinct claws; and the tail is blunt.

There is only one species, *C. Mexicanus*, which is about eight or ten inches long, and as thick as the little finger. It is marked with about two hundred and twenty rings of scales, which form a half ring on the upper part of the body, and another on the under, meeting each other at two lateral lines, which are very straight and very definite. There are two lines of pores on the under part of the body; the tongue is a little extensible, and terminates in two small horny points; its ears are covered with the skin, and consequently not visible externally. It is of a flesh colour, and in this, in its general appearance, and its being possessed of only one large lung, it approaches in character to amphibæna among the serpents, but in its skeleton it is very different. The bones of its two feet are well developed, having distinct blade-bones, and being supported by clavicles butting against a small sternum. Thus it can use its two feet with great dexterity in walking, in climbing, and in grasping. Altogether this is one of the most singular animals with which we are acquainted, and the different parts of its organisation would lead to the placing of it in very different parts of the system. The bones are understood, though this point has not been very well ascertained, to resemble, in their general texture, the bones of warm-blooded animals more than those of reptiles, while the general external characters bear at least some resemblance to those of the lizards, and respiratory system to that of the serpents. This animal is understood to be entirely insectivorous, and it is perfectly innocuous.

CHISMOBRANCHIATA (Blainville). Second order of the second class of molluscs, *Paracephalophora*. The animals of this order possess aquatic organs of respiration, branchial or pectinated, placed at the anterior part of the back, in a large cavity, communicating with the ambient fluid by a large oblique, anterior slit. Mouth without teeth, but the lower part furnished with a lingual muscle; some are without shells, some are interior or external, very flat, aperture very large, entire, and without a columella. This order includes the genera *Coriocella*, *Sigaretus*, *Cryptostoma*, *Oxinöc*, *Soumatella*, and *Volutina*. The order is composed of shells, all of which are marine, and the animal probably herbivorous.

CHITON (Linnæus, Cuvier, &c.) This singular mollusc has undergone no change by the arrangement of modern naturalists; its characters are so well defined, and possess so few variations, that it cannot by any possible chance become blended with other genera. It is a genus perfectly distinct from all other of the animal series; they seem to form the transition from molluscs to insects. The separation of this genus into small natural groups is attended with much difficulty; it may, however, be ultimately accomplished by careful study of the animal and its

covering. The only certain guide hitherto pursued, are the sides of the valves, and the number of tooth-like processes each presents, when detached from the membranous substance which surrounds them; the striae, granulations, punctures, and other external markings, also assist in classing the species. Lamarck observes respecting this well known but singular mollusc, that it seems more like an univalve than a multivalve, and should only be considered an elongated shell, with the testaceous portions of it transversely broken by nature, at its first formation, into a number of distinct moveable parts, in order to facilitate the animal's motion. These valves or testaceous portions may be considered never to vary in characteristic marks, beyond eight in number, though instances have been met with of specimens with only seven. These are inserted at the lateral extremities by certain toothed processes above alluded to, into a tough ligament surrounding the outer margin, firmly uniting them together in their proper position; this ligament is sometimes fleshy, coriaceous, smooth, wrinkled, covered with scales, or beset with tufts of hair; and in one species *Chiton spinosus*, it has numerous tubular, slightly curved, long thin black spines; a tough internal membrane connects the under part of the valves or portions, allowing the animal to contract its shell in a globular form or fully to expand it. When these valves are all united on the animal's back, they form an elliptical shell, the centre part of which is more elevated than the rest; the valves slightly overlap each other, and each succeeding one is less convex towards the margin. One species has callous adhesions longitudinally placed on the back of the valves; some are elegantly marked by the arrangement of their striae, granulations, &c. The interior of the valves is generally white, but some are green, and one species a bright rose-colour; they adhere to rocks covered by the sea, to the backs of tortoises, fishes, or other marine objects, and so fast do they retain their position by exhausting the air beneath their bodies, that it requires a strong lever to detach them, frequently breaking the shell before the animal can be forced from its position. The name chiton, is derived from the Greek, and means a coat of mail. The animal in its structure is not less singular than the shell; its body is more or less lengthened, depressed, or sub-cylindrical, obtuse equally at both ends; the abdomen provided with a muscular disc or foot, adapted to climbing, but most particularly to adhesion; the back is sub-articulated, and corresponds with the different valves; the mouth is anterior, and beneath, in the middle of a considerable mass; it has neither eyes, tentacula, or jaws, but it has a sort of straight tongue in the buccal cavity, bristled with denticules. The organs of respiration are branchial, and formed by a succession of small branchiæ beneath the turned edge of the mantle, particularly at its back part. De Blainville places the chiton in the second class *Polyplaxiphora*, of his sub-type of *Malentozaria*, and he subdivides the genus into the following well-defined species:—1st, Such as are depressed with large valves, carinated, much imbricated, the intermediate ones presenting well marked lateral areas, the limb of the mantle regularly scaly, without hairy or silky tufts, as in the *C. squamosus* here figured. 2ndly, The sub-depressed species, with valves not carinated, much imbricated, and without marked areas, the lateral portions of the mantle covered with a species

of hair or calcareous tubercles, as in the *C. marmoratus*. 3rdly, The species, whose form are similar to the preceding, the valves generally smaller, all the terminal ones much imbricated, without marked areas; the lateral portion of the mantle either quite naked, or as if coriaceous, as in the *C. piceus*. 4thly, The species more or less cylindrical, vermiform, nearly naked; the foot very narrow, as if articulated; the branchia in the posterior half of the body only; the valves very small, often separated or not imbricated, and always visible, as in the *C. laevis*, constituting Lamarck's *Oscabrella*. 5thly, The species with the valves narrower, imbricated, without distinct areas, the lateral parts of the skin naked or hairy, but always furnished with tufts of silk or hair, arranged in pairs, as in the *C. fascicularis*; and lastly, Such species as are more or less cylindrical, vermiform, nearly naked, the valves of the shell very small, almost entirely concealed beneath the skin, with tufts similar to the preceding section, as in the *C. larvæformis*, which constitutes Lamarck's genus *Chitonellus*. These shells sometimes attain a large size, measuring four inches in length; but they usually do not exceed two inches. They are found in every sea, the larger ones in warm latitudes; but the shells of the last division have only as yet been found in Australia. One of a small size is found on the British coast. Fossil species are rare, but detached valves are sometimes met with in the calcareous sand formation, in the neighbourhood of Paris.

**CHITONELLUS** (Lamarck). A species of mollusc, forming one of the divisions of the genus *Chiton*, of De Blainville's system (which see). It inhabits the coast of New Holland, and from its external valves never being interlocked, it has the power of moving laterally as well as forward.

**CHITONIA** (L. Don). Handsome shrubs and trees, natives of South America and the West Indies. Linnæan class and order, *Decandria Monogynia*; natural order, *Melastomaceæ*. Generic character: calyx of four parts, deciduous; petals orbicular; stigma pellate and hemispheric; seed vessel four-celled, four-valved; seeds two in each cell; arillo fleshy and banded. The plants of this genus were formerly included in the genus *Melastoma*, but have been separated by Mr. D. Don.

**CHIVES**. A diminutive species of the onion tribe, called by botanists *Allium schænoprasum*. It is not bulbous; but grows in thick tufts, producing an abundance of slender delicate leaves, having the true onion flavour, and very useful in dressed salads, when small green plants of the common onion are not to be had. There is, or always should be, a small bed of chives in the herb border, the leaves being often useful in cookery, as well for garnishing as for salads. There should also be a few pots of chives kept in every garden, in order to be placed in a hot-bed or hot-house, to afford a supply during winter. In the open ground they require to be frequently cut off, to induce a fresh growth of leaves. Chives are propagated by divisions of the root, and like a shady situation.

**CHLÆNIUS** (Bonelli). A very extensive genus of *Coleopterous* insects, belonging to the section *Pentamera*, family *Carabida*, and sub-family *Harpalides*, and to that subdivision in which the anterior tarsi alone of the males are dilated, the basal joints being large, square, or rounded, or the *Patellinæ* of Dejean. The palpi are rather long, with the terminal

joint slightly oval, squared off at the tip; the tooth at the middle of the chin is bifid, and the three basal joints of the males are dilated. These insects are amongst the most elegant species of the family, being ordinarily of a fine opaque green colour, and clothed with a down, whence their generic name; some few species have, however, the body smooth and shining. They appear to be distributed over the whole surface of the globe; none, however, are yet recorded to have been found in New Holland. They emit a very powerful and disagreeable alkaline odour. The Count Dejean has described sixty-six species in his "Species Général," but in his new catalogue there are 115 belonging to this genus. There are seven or eight British species, of which the *Carabus marginatus*, Linnæus, (*Vestitus*, Fabricius,) is the most abundantly met with. Their habits do not materially differ from the other allied genera.

**CHLAMYPHORUS**. A genus of mammalia belonging to the order *Edentata*, and nearly allied to the armadillos, though different from them in many respects. The characters are: ten teeth of uniform size; five toes on each of the feet, with nails on the fore feet very strong, crooked, compressed laterally, and forming very powerful weapons either for digging or for defence. The back is covered with a succession of scaly pieces ranged transversely; but there is no shell either at the anterior or the posterior part, as is the case with the armadillos. These pieces are attached to the spine only. The animal is not above five or six inches long; like the rest of the tribe it is found in the interior of South America, and it spends the greater part of its time under ground, for burrowing in which its powerful claws on the fore feet are well adapted.

**CHLAMYS** (Knoch). A genus of *coleopterous* insects, belonging to the section *Tetramera*, and family *Chrysomelida*, comprising a considerable number of minute but curious species from Brazil, having the body short and very irregular above, the head vertical, the antennæ short and serrated, and the labial palpi furcate. Two excellent monographs of this interesting genus have been given by Messrs. Kollar and Klug; some of the species have the appearance of morsels of rough precious stones, being of a rich metallic colour. In their habits they are, probably, herbivorous, like the majority of the family to which they belong.

**CHLENACEÆ**. A natural order of dicotyledonous plants, containing five genera and eleven known species. Many authors consider this order as allied to the mallow tribe, on account of its involucreted flowers, and monadelphous stamens. Jussieu however thinks that, in consequence of its petals coalescing at the base, and its seeds being albuminous, it bears an affinity to *Ebenaceæ*, or the ebony family. The plants of the order do not seem to be sufficiently well known to enable botanists to determine their exact position in the natural system. The essential characters of this order, as given by Decandolle, are: involucre one to two-flowered, persistent, varying in form and texture; sepals three, small; petals five to six, hypogynous, broad, and sometimes slightly coalescing at the base; stamens sometimes numerous, at other times only ten; filaments somewhat combined into a tube at the base, or adnate with the tube of the petals; anthers two-celled, roundish, adnate or free; ovary single, three-celled; style one, filiform, stigma triple; capsule three-celled, or by imperfection only

one-celled; seeds solitary or numerous, fixed to the centre; albumen fleshy or horny; embryo green, central; cotyledons foliaceous, waved.

The plants belonging to this order are small trees or shrubs, with alternate, stipulated, entire leaves, and paniculate or racemose flowers. They are almost all natives of the Island of Madagascar. The genera of the order are *Saccolena*, *Leptolena*, *Schizolena*, and *Rhodolena*. To these Decandolle has added the East Indian and Mauritian genus *Hugonia*, which he considers allied to the order *Chlenaceæ*, but differing from it in being destitute of an involucre to the flower. This genus is also allied to *Malvaceæ* and *Byttneriaceæ*, but is distinguished from them in having an imbricated, not a valvate, calyx.

Very little is known in regard to the properties of the plants of this order. *Leptolena multiflora*, and the species of *Schizolena*, are handsome small trees with fine flowers, while *Rhodolena altivola* is a climbing shrub, with large purple flowers. The genus *Hugonia* was named by Linnæus in honour of Dr. Augustus John Hugo, of Hanover, who was a great friend of Haller. *Hugonia mystax*, a native of Ceylon and Malabar, is a slender shrub twelve feet high, with numerous short leafy branches, each of which bears about its middle a pair of remarkable revolute spines. The resemblance of these to a pair of *moustaches*, is said to have given origin to the specific name *mystax*. The plant bears yellow flowers, and a shining fruit, containing a red tasteless pulp. The wood has a reddish-brown colour, and possesses an aromatic odour. The root has been applied externally to inflammatory swellings, and also to the bites of the hooded snake (*Coluber naja*). Internally it has been recommended in worms and the febrile diseases to which children are liable.

**CHLIDANTHUS** (Herbers). An ornamental and highly fragrant bulbous plant, introduced from South America in 1820. Linnæan class and order *Hexandria Monogynia*; natural order *Amaryllidææ*. Mr. Sweet observes of this plant, that it requires no water when not in a growing state; and if planted in the open borders in spring it will flower in the summer, but must be taken up in autumn, and kept dry through the winter; or if left in the ground requires covering from frost.

**CHLORA** (Linnæus). A genus of two annual plants, one of which, *C. perfoliata*, is a native of Britain. They belong to the natural order *Gentianeæ*.

**CHLORANTHÆÆ**. A natural order of dicotyledonous plants, containing three or four genera, and a few species. It is nearly allied to *Piperaceæ* and *Laurineæ*, but differs from these orders in the absence of a sac to the embryo, and in having a pendulous ovule, and opposite leaves with intermediate stipules.

The following are the botanical characters of the order: flowers naked, spiked, perfect or unisexual, subtended by a scale; stamens lateral, if more than one, connate, definite; anthers one-celled, bursting longitudinally; filaments slightly adhering to the one-celled ovary; stigma simple, sessile; ovule pendulous; fruit a drupe, indehiscent; embryo minute, placed at the apex of a fleshy albumen, with an inferior radicle.

The plants belonging to this order are herbs or under shrubs, with jointed stems, opposite simple leaves and terminal green flowers. They are inconspicuous, and are not considered as ornamental in gardens. They are found in tropical regions, and

inhabit the hot parts of both the East and West Indies, as well as South America. They have generally an aromatic taste, and possess stimulant properties. The chief genera of the order are *Chloranthus*, *Hedyosmum*, and *Ascarina*.

*Chloranthus* is the genus which gives name to the order. The whole plant of *Chloranthus officinalis* has a fragrant aromatic odour, which is lost by drying. The roots of the plants however retain, even when dry, a smell like camphor, and have a bitter aromatic flavour. They possess heating and stimulant properties, and may be used in place of snake-root in promoting the action of the skin and kidneys. The root of *Chloranthus inconspicuus* has the odour of seneka root, and is said to possess similar qualities. The leaves of the plant are used in decoction, for the cure of intermittent fever.

**CHLORANTHUS** (Swartz). A genus of three Chinese herbs and under shrubs, bearing green-coloured inconspicuous flowers, but having an agreeable scent, for which they are kept in stoves and propagated by cuttings.

**CHLORION** (Latreille). A beautiful genus of hymenopterous insects, belonging to the division *Fascesores*, and to the family *Sphegidae*, or sand-wasps. The body is rather long, highly polished, and metallic; the head broader than the thorax; the antennæ inserted close to the mouth, and the second submarginal cell narrow, especially near its union with the marginal cell; the tarsal claws have a tooth near the middle. These splendid insects are above the middle size, and owe their generic name to the brilliant metallic green colour with which they are adorned. The habits of one of the species of this genus, *Sphex lobata*, Fabricius, were observed by M. Cossigni, who states that it is a rare insect in the Isle Bourbon, although very common in the Isle of France; it flies with rapidity, entering the houses, flying about the window-curtains, and creeping into their folds; when settled it is easily caught: but great caution must be used, as it is provided with a sting even more powerful than that of the bee, this fly protruding its weapon to a greater distance than the bees ordinarily do. In the Isle of France the domestic bees are not observed, although they abound in the woods of the Isle Bourbon; their rarity in the former instance being attributed to the presence of the chlorions, which drive them away. M. Cossigni observed an encounter between a cockroach and a chlorion. After regarding each other for a moment, the latter pounced upon the blatta, seizing its head with its jaws, and curving its body so as to sting the belly of the cockroach. When it had effected this, it dismounted, quitted its victim until the poison which it had introduced into the wound should have begun to operate, when it returned, seized it by the head, and, dragging it along backwards, deposited it in a hole in the wall. When its prey is too large to enter the aperture, the chlorion deliberately clips off its wings and wing-cases, and even its legs, so as to enable it to force it into the burrow. The object of this slaughter is the laying up of a sufficient supply of food for the future progeny of the chlorion; hence, as is generally the case in insects, the task devolves upon the females, and, indeed, it is this sex alone which is provided with the powerful sting which is so important an instrument in the operation. We have detailed a somewhat similar course of proceeding in the *CERCERIDES*. See our article upon this group.

**CHLOROPS** (Meigen). *Oscinia*, Latreille. A genus of dipterous insects, belonging to the section *Athericera*, and family *Muscidae*. The head is nearly spherical; the legs are of moderate size and thickness, and the body short and not filiform; the antennæ are short, and have the seta not branched. These insects, which are of small size, are amongst the most obnoxious of the diptera, attacking various kinds of corn, and almost equalling in their ravages the *Cecidomyia*. They are of small size, smooth, polished, and of a black colour more or less variegated with yellow. To this genus belong the *Musca Frit* of Linnæus, and the *Musca pumilionis* of Bierkander, together with upwards of twenty other British species. The first of these insects, although stated by Messrs. Kirby and Spence not to have been discovered in Britain, is doubtfully introduced by Mr. Stephens into his Catalogue of British Insects. This fly, according to Linnæus, occasionally destroys in Sweden not less than a tenth part of the crops of barley, the loss being estimated at 100,000 golden ducats. The mischief is effected by the insect getting into the ears. An interesting account of the chlorops pumilionis is given by Mr. Markwick, with additional observations by Mr. Marsham, in the second volume of the Linnæan Transactions. This insect was at first considered as the Hessian fly, and no small alarm was produced in consequence thereof; but the latter author, by pursuing a series of observations by which the real species was determined, proved the incorrectness of such a supposition. Early sown wheats are especially liable to the attacks of this fly, the grub of which feeds within the principal stem, just above the root, thereby entirely destroying it; the root, however, throws out side shoots, so that the injury is not so great as it was at first supposed that it would have been. The perfect flies, as we have stated in our article on the *Cecidomyia*, abound in the autumnal months\*, swarming in our apartments, so that, from the short-lived existence of dipterous insects in the perfect state, it seems necessary that, as the flies are produced from the early sown wheat in May, there should be an intermediate generation to produce the autumnal brood; direct observation is, however, required upon this point. This insect is under a quarter of an inch in length, the thorax having two lateral yellow lines. The maggot is white and fleshy. It is at the period when the wheat is about six or eight inches above the ground (as we learn from a friend who has lately reared some of those destructive insects), that the chief injury is committed.

**CHLOROXYLON** (Decandolle). A lofty East Indian tree, called *Swietenia chloroxylon* by Roxburgh. It is the green mahogany of the east, and as useful timber is estimable for many purposes of building. Chloroxylon is also the specific name of one of the West Indian laurels.

**CHOANITES**. A name given by Mr. Mantell, in his Geology of Sussex, to a genus of fossil zoophytes, which are very numerous, and appear to hold an intermediate place between the *Alcyonia*, properly so called, and the *Ventriculites*. They are distinguished from the former by their having a central cavity in their upper part, and, from the latter, by their being without an external reticulated integu-

ment, &c., and possessing a very slight degree of contractile power. Their forms are various, being generally either funnel-shaped, spherical, globular, or subcylindrical, having a central opening in their superior part, and appearing to have been originally composed of a parenchymatous substance, capable of imbibing moisture, and of contraction in a slight degree. The base was fixed.

The *Alcyonium ficus* of Linnæus may be considered as the type of this genus. Parkinson, in his Organic Remains, describes this zoophyte as follows:—"It is of the form of a fig, being attached to rocks by branches proceeding from its smaller end; the upper part is a little flattened, and has a cavity in the centre. Its colour resembles that of tobacco, and its parenchymatous substance cannot be compared to any thing better than to nut-galls when well dried." *Org. Rem.*, vol. ii., p. 96.

The remains of this genus, which were formerly indiscriminately placed among the *Alcyonia*, were first noticed by M. Guettard, at Verest, and at Mont Richard, in Touraine, and were described by him in a paper published in the Memoirs of the Academy of Sciences of Paris, 1757.

He observes that they are of a globular form, having in many examples the base elongated into a pedicle. In the centre of the superior part is a circular opening, generally filled with the substance in which the fossils are embedded. The cavity is larger in its upper part than in the lower, and is continued almost to the pedicle, in some specimens appearing even to pass through it. From the circumference of the opening, lines may be traced that not only pass over the whole of the spherical part (where they form striæ more or less distinct), but also penetrate the substance of the zoophyte. There is seldom more than one opening, but instances have occurred in which three have been found. Very accurate representations of these fossils are given in Parkinson's Organic Remains, vol. ii., pl. 9, figs. 1, 3, 4, 6, 8, and pl. 11, fig. 8.

Three species are described by Mantell. The first of these, the *Subrotundus*, is that generally termed by collectors the *Picoid alcyonite*, from its supposed resemblance to the fig. The surface is smooth, and entirely without markings, and the cavity nearly circular. The second, the *Flexuosus*, is cup-shaped, the margin of the central depression being marked with flexuous indentations. The radical processes are all long and fibrous. This species is very rare, and, as well as the former one, is found in the Upper Chalk, near Lewes in Sussex. The *Konigii* is the third, and is described as "inversely conical, externally marked with irregular fibres, some of which penetrate into the substance of the fossil, and terminate in openings on the inner surface. The central cavity is cylindrical, deep, and narrow, and the base fixed by the radical processes." This species is generally enveloped in large irregular flints, which exhibit but slight traces, externally, of the body which they inclose. The superior part presents a convex surface, with a cylindrical body in the centre, whence interrupted fibres ramify in a radiating manner towards the margin. Numerous perforations may also be observed at the base, which, without doubt, afforded a passage for the radical processes. They are found in abundance in the loose flints beneath the turf, near Lewes race-course, and appear to have been of frequent occurrence in the upper beds

\* During the autumn of 1834, they literally swarmed in apartments, even in the immediate environs of London.

of the chalk, although they are now very rarely found in the quarries in that neighbourhood.

**CHOCOLATE NUT** is the *Theobroma cacao* of Linnæus. See *THEOBROMA*.

**CHOLEVA** (Latreille). A genus of coleopterous insects, belonging to the section *Pentamera*, and family *Silphidae*. This genus, together with those of *Catops*, *Plomaphagus* and *Mykechus*, form a small group, distinguished by their small size, and great agility; the antennæ with the club five-jointed, the eighth joint being very minute, and the elytra rounded at the tips. Mr. Spence has published a monograph upon the group in the Linnæan Transactions. The insects are of dark and obscure colours, frequenting dry bones, putrid fungi, and vegetable matter in a state of decay. There are numerous British species.

**CHOMELIA** (Jacquin). West Indian shrubs, formerly called *Ixora* by Lambert and Swartz. Linnæan class and order, *Tetrandria Monogynia*; natural order, *Rubiaceæ*. Generic character: calyx tubular, limb four-cleft, recurved; corolla tube long, cylindrical, limb in four divisions, spreading points of the divisions acute; stamens with short filaments inserted in the tube; anthers linear, and somewhat prominent; style filiform; stigma in two spreading processes; drupe oval, containing a four-furrowed two-celled nut, each cell one-seeded. This genus being nearly allied to the *ixoras*, also partakes of their ornamental character.

**CHORAGUS** (Kirby). A minute genus of British coleopterous insects, of whose family entomologists are at variance. It is of an ovate form, with the head deflexed, the antennæ long and terminated by a club; the legs are short and of a moderate thickness, nevertheless the insect possesses the power of leaping in a remarkable degree. Mr. Kirby, by whom it was first described, thought it allied both to *Cryptoccephalus* (from the length of the antennæ and form of the body), and *Cis* (from the former being clubbed). Mr. Stephens places it amongst the *Plinidae*, whilst M. Robert has recently figured it as an *Anthrribus*, a genus allied to the *Bruchidae*. It is found amongst grass and low herbage, but is very rare.

**CHORIZEMA** (Labillardiere). A genus of beautiful shrubs, natives of New Holland. Linnæan class and order, *Decandria Monogynia*; natural order, *Leguminosæ*. Generic character: calyx two-lipped, upper one cleft, lower one trifid; corolla keel bellying, wings short, style short; pod swollen, many-seeded, nearly sitting. These are extremely neat greenhouse plants. The *C. Henchmannii* deserves a place in every collection. They are propagated by cuttings.

**CHRISTMAS ROSE** is the *Helleborus niger* of Linnæus. One of a herbaceous family of plants indigenous to Europe, and long introduced into gardens on account of their early flowering. The whole of the hellebores are said to contain poisonous principles in a greater or less degree, though some of them are very fragrant. The flowers generally appear before the leaves, and are some of the first gems of the spring. They are propagated either by dividing the root or by seeds.

**CHRIST'S THORN** is the *Zyziphus spina Christi* of Willdenow. It is a native of Egypt, and is cultivated in our greenhouses, and easily increased by cuttings.

**CHROMIS**. A genus of spinous-finned fishes

belonging to the family *Labroides*. Their general characters are: their lips and intermaxillary bones contracted; a single dorsal fin with two produced filaments, teeth set like those of a card on the jaw bones and the palate, their lateral ones intercepted, the ventral fins produced in long threads. There are numerous species, several of which are occasionally found in the British seas. They are not of large size, but they are esteemed as food. For some detail of them, the reader is referred to the article *LABROIDES*.

**CHONDROPTERYGII** (CARTILAGINOUS FISHES). An order or rather sub-class of fishes which differ so very much in many of their essential characters from the rest of the finny tribes, that naturalists have sometimes described them under the name of reptiles rather than fishes. But still, how much soever they may differ from the other inhabitants of the waters, they are decidedly fishes, only it is not easy to trace a gradation either from them to the others, or from the others to them. In some parts of their organisation they are no doubt inferior to the bony fishes, but there are some others in which they are decidedly superior.

They differ greatly in the several divisions of the sub-class; but they all possess that general cartilaginous texture of the bones, on account of which the name has been given them. This character varies much however in the different genera, so that it is not possible to frame a general description, so that it shall be strictly applicable to any one species. In general, we may say that they have some resemblance to that division of the soft-finned fishes, to which Cuvier very accurately applies the name of *plectognathes* or "soldered jaws"—because these fishes have the bones of the mouth united to each other, and consequently comparatively little motion of that organ. There is another approximation in that family to the sub-class now under consideration, namely, a tendency to produce upon the skin, not scales as in the other bony fishes, but grains or tubercles of osseous matter.

The chondropterygii have all the bones, forming the cranium or cavity containing the brain, united into a single piece, but still there are markings which indicate portions resembling those that are united by sutures in other fishes, though in some these markings are almost entirely obliterated, and the whole skull consists of one case of flexible bone. The vertebral column may be said generally to consist of one single flexible piece, though in this also there are differences, some having articulations marked throughout its length, and even tolerably distinct apart, while in others, as in some of the *cyclostoma*, "round mouths," or suckers, there is scarcely any indication of a joint even by a simple marking; so that these may be regarded as, in their skeleton at least, being at the very bottom of the scale of vertebrated animals, and connecting them with some of the most simply formed tribes in the whole animal kingdom, the *myxine* or hag being as much like a slug or leech as a fish, although it has still the general character and economy of a vertebrated animal.

But it is in the general texture of the bone, rather than its form, that the distinguishing character of these fishes consists. In all other vertebrated animals the bones are made up of plates, and these plates of fibres, which extend in the direction of the length of the bone, so that the bone is much more easily split in length than broken across, whereas in the chon-

dropterygii, whatever of osseous matter, or earthy salts, is formed in the cartilaginous matter, forms in grains, which are detached from each other without any appearance of being organised in any direction.

The bones, even of those animals which have the skeleton hardest and most perfect when mature, are cartilaginous when they are young, and they ossify gradually, requiring a longer or shorter time in different races of animals; but, when ossification begins, always begins at points, and proceeds from those points as centres, in lines of definite arrangement, the characters of which are worthy of more attention than they have hitherto received. Thus there is in the cartilage of these animals, a principle by means of which it can organise the earthy parts of the bone, as well as produce them, whereas, in the fishes under consideration, this principle seems to be entirely wanting; and therefore, though the general cartilaginous basis of the bone may be considered as a product of organisation, the hard matter which may afterwards be imbedded in it, is not so imbedded in consequence of any particular law of organisation. In this respect therefore, we may with perfect correctness say, that these fishes are a stage lower in the structure of their bones than any other vertebrated animals. It seems also that their cartilage is differently formed. The cartilage of the others is to a considerable extent fibrous, though the fibres are not easily perceptible, in consequence of the closeness of their union; and we may suppose that the reason why the bony matter in this sub-class of fishes is not organically arranged, is the absence of this structure in the cartilaginous basis. Therefore, though the term "cartilaginous" answers very well for distinguishing them from other fishes, we must not suppose that they have the same kind of cartilage as the others only without the bony matter in it; for their cartilage is not only really but necessarily different. If it were the same in substance and in arrangement, it would be impossible not to suppose that it would ultimately ossify into the very same kind of bone. If we were not to conclude that the same preparing substance would, and must, under the same circumstances, produce the very same result, then we could come to no conclusion whatever, and there would be an end to natural history as a science.

Imperfect as the bony structure of these fishes thus seems, it has its advantages. They move more freely than animals with stiff bones; they are much less liable to injury; and so far as we know, they are exempted from old age, from decay, and probably from death, except by casualty.

In all cases where the bones of the vertebral column are stiff, the motion of the joints is confined to certain directions only; and though some vertebrated portions, as in the necks of many birds, and more especially in the *chelonia*, which have hard shells, have very beautifully formed joints, and admit of a wonderful degree of flexure, yet in them the flexure is produced by every different joint being bent in a different direction, there being as many centres of motion as there are joints, and consequently a very complicated apparatus of muscles for moving them. The bones of the true serpents (we are of course speaking of the vertebral column only), and those of bony fishes, afford instances of motion which is more free and more general in its direction; but still the principal motion is referable to a definite plane in the body of the animal. That of the serpents is

vertical, passing through the middle of the back and the belly, and there is generally a distinct mesial line along one or both. The bony fishes again are articulated, so as to have their principal motion in the horizontal plane passing through the middle of the sides, which are generally marked by lateral lines. The joints in these are without processes, upon which a particular motion can be performed as on a centre, for they consist of two hollow conical cups, with their lips applied to each other, and their cavities filled with cartilaginous substance, so that each of them may be considered more or less as a universal joint, though this is modified in different species, in such a manner as best adapts them to their habits; a bone of this kind is obedient to the action of the general muscular mass in which it is embodied, and does not need detached muscles for the motion of every single joint, attached at each extremity to one of the bones which meet at the joint, in the same manner as in animals which have the bones articulated upon each other by means of processes and cavities. The muscles of fishes act between the bone and the skin, as their two principal points of insertion; and as the skin is supported externally by the weight of the element in which the fish moves, much less muscular exertion is required to produce motion, than in animals which have the bones with regular joints.

In the cartilaginous fishes, this facility of motion is communicated to the whole of the vertebral column, so that they can move with still less of muscular effort than the true fishes. Thus they have great command of themselves in the water, without much exhaustion of their system; and as there is at the same time no positive limit to the growth of their bones, they are exempted from old age and decay.

This leads us to another peculiarity of their structure, their respiratory system. The quantity is proportionately less than that of bony fishes, and their breathing apparatus is of more simple structure. In consequence of this, the whole functions of life in them are carried on with less exhaustion of the system than those of the other fishes; and thus, while their body is less worn by the operation of living, it requires less renovation, the principle of life in it is more durable, they can bear abstinence for a greater length of time, can feed more voraciously when they do feed, and more of the substance of their food can go to the increase of their size. These particulars vary much in the different divisions or orders into which they may be divided, and also in the subdivisions, but still they, to some extent, apply to the whole.

There is this further to be remarked on them generally, that their organs and manner of reproduction are much more perfect than those of the other fishes, that in these respects they bear a considerable resemblance to reptiles; and some of them have even a physiological, though not a structural, resemblance to the marsupial mammalia. In describing them according to their feeding apparatus, which, however, is much less satisfactory in the case of fishes than in that of any other vertebrated animals, the most remarkable circumstances are the absence of maxillary and intermaxillary bones for supporting the teeth. But the teeth, though they are without bony supports, are not the less powerful; for some of these fishes, as the shark for instance, have more formidable mouths than any other animals. The teeth are

moveable; and as they are generally in several rows, they can hold on with one part, and cut and tear with another; and if we except those fishes which feed upon crustacea or sea-weed, they are perhaps the only ones which divide their food by the action of the mouth.

The skin is a very important part of the structure of these fishes, and may be said to contribute almost as much to support them in their motions as the bony part of their structure. Indeed the skin is almost the only part in which any substance approaching to the character of bone is formed. Some of them produce large plates as in the sturgeons (see the article ACCIPENSER), others hooks and spines, some of which are very formidable weapons, and others tubercles of various forms and sizes. The various species of shagreen which is used for covering boxes and various other articles are the skins of sharks. These bony appendages are exceedingly hard in their consistency; but whatever may be their form, they partake of the general character, which we have already alluded to as distinguishing the internal bones—they do not exhibit a fibrous structure, but are uniform throughout; and though it is difficult to divide them in any particular direction, they are equally divisible in all. These fishes are divided into two sub-orders, those which have the gills fixed, and those which have the gills free.

WITH FIXED GILLS. In these the gills adhere to the skin, or rather to the integument of the sac in which they are contained, instead of being loose at their posterior edges, as is the case with other fishes. The water does not therefore pass through the gills of these fishes as it does through those of others; neither have they any gill-lid, or *operculum*, by the action of which they carry on the operation of breathing. They have between every two fringes or leaves of the gills, an opening for the admission of water, and the outer edge of each gill is supported by a cartilaginous arch imbedded in the flesh, between the openings; and it is by means of the muscles acting on this arch, that the process of breathing, which is a very slow one, is carried on. The genera and species of this order are much more numerous than those with free gills. They consist of two families, *PLAGIOSTOMUS*, "oblique mouth," or "cross mouth," the mouth being in the form of a slit under the snout, which generally projects a considerable way in front of the opening, and the mouth, from the absence of jaw-bones, admits of a great deal of motion; and *CYCLOSTOMUS*, "round mouth," from the mouth being in the form of a sucker, or capable of turning backwards so as to be on the same plane all round. Some notice of each of these families will be given under its name in the order of the alphabet.

WITH FREE GILLS. These have their gills free at the one extremity, as is the case in ordinary fishes, and they have only a single gill opening, for allowing the water to escape. This opening is furnished with a gill lid; but without any flap. This sub-order consists of four genera, though all these may be included in one family, the sturgeon family. See *STURIONIDÆ*.

Of these two orders or sub-orders, those with fixed gills may be considered as the most typical; but both stand so distinct from the rest of fishes, that, with the exception of the partial resemblance to *plectognathes* above alluded to, they must be considered as forming, not a subdivision of fishes considered as one class of animals, but as a distinct class of fishes, which

hold a very peculiar place in the structural system of animals, and also from their numbers perform an important part in the living economy of the waters.

We must not suppose that there is any thing out of nature, in there thus being two distinct classes of vertebrated inhabitants of the waters, any more than that there should be different species; for we have a similar division of mammalia; the marsupial animals being as distinct from the other mammalia, as the chondropterygii are from the other fishes. We have mentioned that there are some points of relation between those second classes of mammalia and of fishes, and one would be almost led to believe that they are portions of a different creation from the other classes, which they resemble in their common economy and habits. It is exceedingly difficult, however, to trace the analogies between sea and land animals, not only from the great ignorance in which we must for ever remain as to the details of what goes on in the deep, but because many links in the chain are wanting.

CHRYSLIS or AURELIA. Under these terms is designated the pupa state of lepidopterous insects. Having already, in our article AURELIA, given some account of the cause of the application of these terms to this state, and in one article, BUTTERFLY, detailed the peculiarities of the chrysalides of the *Papilionidæ*, we shall here briefly notice some general circumstances relative to chrysalides in general, and to those of moths and hawk-moths in particular, reserving to the article COCOON our account of the construction of those curious envelopes in which the insect is often in this state inclosed.

The pupæ of lepidopterous insects entirely differ from those of every other order of insects, a circumstance of some interest as well as peculiarity, since in other instances we find the pupæ of several orders exhibiting the same general form. In the *Lepidoptera*, however, the various organs of motion of the future insect are laid along the breast and sides, but are folded up under a hard skin, whence they are much less distinctly perceptible than in the pupæ of other insects. Linnæus has termed this an obteated pupa. In general lepidopterous chrysalides are of an oblong-oval form, obtuse at the head, and gradually becoming narrow towards the tail; but in some moths, as in the *Bombyx luna*, the form is shorter, and obtuse at each end. Under this form the insect appears neither to have legs nor wings, it seems even destitute of life, taking no nourishment and appearing like an unorganised mass, the only sign of life being a slight occasional twitching of the hind part of the body. The outer covering appears of a cartilaginous nature; it is commonly smooth, but in some few instances it is hairy. From the blunt extremity of the body are to be observed various small and narrow compartments, arranged like the bands of a mummy. These are the coverings of the legs and antennæ, disposed along the breast, the part from whence they seem to arise is the head, which is covered by a piece termed the *Cephalotheca*. On the outside of these narrow bands are to be observed two broader scales, which, covering the wings, are termed *Pterotheca*, arising from the opposite side to the breast, and which is the covering of the thorax, or *Cylotheca*. This is followed by the abdomen-case, *Gastrotheca*.

The chrysalis, upon quitting the exuvia of the caterpillar, is soft and tender; by degrees, however,

its external envelope becomes hard and friable. Moreover the surface of the body is at first moistened with a viscid fluid which exudes from beneath the wings, and the other parts which are inclosed between these organs, and which becomes thickened and hardens rapidly, and in so doing glues together the contiguous parts, which are consequently now inclosed in an additional envelope, this taking place within twenty-four hours after the change; at the same time also this fluid not only loses its transparency, but also acquires a colour. Previous to the hardening of this fluid it is easy to observe as well as to separate the various external organs of which the future butterfly is composed, as the antennæ, legs, wings, &c. There is this difference, however, between the chrysalis and the imago; at least of the butterflies; in the former state one pair of wings, the upper, are alone to be observed, the second, or inferior pair, being hidden beneath them, the intermediate space in the pupa being filled with this gummy matter, by which they are at length glued together; whereas in the butterfly (but not in the moths, except during flight) the lower pair of wings are exposed, even when the butterfly is at rest upon the bosom of a flower.

Reaumur has divided chrysalides in general into two great divisions, namely, those which, from having various angular projections upon the body, he has termed angular chrysalides, and those in which the body is smooth and unfurnished with these projections, and which may be termed conical chrysalides, but which Reaumur calls "feves;" and it is a curious circumstance, that all angulated chrysalides produce butterflies, whilst from the conical chrysalides, with a few exceptions, the various tribes of moths and hawk-moths are produced; these exceptions being confined to the small butterflies, belonging to the family *Lycanidae*. Moreover the chrysalis of the orange-tip butterfly (*Mancipium cardamine*) seems intermediate between the two groups, having the body boat-shaped, with a spindle-formed process arising from the head, as well as the tail. There is a great difference in the situation of the prominences and angulated projections, upon the body of the chrysalides belonging to the first of these divisions, and in some of the old works of natural history, we find the representations of them fancifully converted into the singular profile of the human face, the dorsal prominence forming the nose! Amongst the conical chrysalides, there are also various differences to be observed; we shall, however, only notice those offered by the sphinx family, in which the tongue, which in the perfect state is exceedingly long, is inclosed in a thickened cylindric proboscis, which stands off from the breast, and within which the tongue is curled up; whilst, in the genus *Calophasia*, Stephens, a provision of a different kind is made for the unusual length of the organ, by the tongue-case being recurved upon the breast, in which respect it approaches the shark moths, *Cucullie*.

In our article BUTTERFLY, we have alluded to the incorrectness of the fanciful notions entertained by the old naturalists, that insects in their progress to the perfect state underwent a series of real metamorphoses. In like manner we may notice, as conveying an equally incorrect idea, that the bursting forth of the butterfly has been adopted as an illustration, fitting to convey a token of one of the profoundest mysteries of our Holy Religion.

Oh, start not! on thy closing eyes  
Another day shall still unfold,  
A sun of milder radiance rise;  
A happier age of joys unfold,  
Shall the poor worm that shocks thy sight,  
The humblest form in nature's train;  
Thus rise in new-born lustre bright,  
And yet the emblem teach in vain!

The idea is highly poetical, but the simile is not correct when the changes undergone by "the poor worm" have had all of the marvellous stripped from them by the assistance of direct observation; and yet these changes are not, on that account, the less wonderful. To them, indeed, may well be applied the celebrated words of the poet—"Truth is stranger than fiction."

The body of the caterpillar consists of twelve segments, exclusive of the head and anus, and on each side of the 1st, 4th, 5th, 6th, 7th, 8th, 9th, 10th, and 11th of these segments, a small oval spiracle or breathing pore is to be observed, making together eighteen. In the pupa, notwithstanding the great alteration which has taken place in the size and disposition of the segments, we notice, besides the head, first, a small, nearly square, piece, being the remains of the first segment, having, on each side, a small breathing pore; next, a large dorsal piece, giving rise to the large anterior wings, which is the second segment; then a short dorsal piece, giving rise to the second wings, being the third segment; after which, follows another short segment, of which the spiracles are not observable, which is succeeded by seven spiraculiferous rings; then comes another ring, without spiracles, and the body is terminated by a plate covering the anal organs. This description is taken from a living male Chrysalis, of the splendid large Emperor moth, *Pavonia major*, an inhabitant of France.

The *Chrysalides* of various moths exhibit a singular circumstance not hitherto satisfactorily accounted for, but which present an interesting instance of that parental care, "which nature so conspicuously manifests towards the most insignificant (if any can be called such) of her productions." The small Eggar moth, *Eriogaster lanestris*, is one of the most remarkable of these species,—doomed to a regular appearance, in the winged state, at the termination of the cold and ungenial month of February, nature (that it may not fail and become extinct) reserves a small portion of it annually, in the pupa state, until the February following that of its pupation, and sometimes even until the third occurrence of that frigid month, denying their emancipation all the intermediate time, and thus effectually securing, by these unusual means, the safety and perpetuation of an animal, small it is true, but whose annual existence, at that inclement season, in the winged state, is probably of more consequence in the intricacy of its great Creator's plans than we are at present aware of, although He constantly exposes it to the dangerous vicissitudes of winter; for

Each shell, each crawling insect, holds a rank,  
Important in the plan of Him who framed  
This scale of beings, holds a rank, which lost,  
Would break the chain, and leave behind a gap,  
Which nature's self would rue."—*Lepidoptera Britannica*.

CHRYSA N T H E M U M (Linnæus). An extensive genus of herbaceous perennial and annual plants, valued for their large showy flowers. Linnæan class and order, *Syngenesia superflua*; natural order, *Com-*

*pusite*. Generic character: anthodium hemispherical, scaly; scales with scarious margins; receptacle plain and naked; seeds oblong and angular. The geographical distribution of this genus extends over all the northern hemisphere, from the British isles to Kamschatka, and from Siberia to Asia Minor. One of the British species, *C. segetum*, was formerly a troublesome weed in corn, inasmuch that land subject to it was lower rented than that where the yellow weed was unknown. By careful hand-weeding, however, the plant is now almost banished from all well cultivated fields. Several are admitted into the flower garden; and since the introduction of the Chinese half shrubby species, every greenhouse, garden, and court-yard, are ornamented with them. Few plants have engaged the attention of florists more than this, and they are now as much admired, and as much cultivated in England, as they are in China. Two monographs have been published of the *C. Sinense*, the first by J. Sabine, Esq., S.H.S. of London, and the second by the late A. H. Haworth, Esq. According to Mr. H., there are above fifty different species or varieties, all of them handsome, and some of them splendid flowering plants. They are what are called *half-hardy*, that is, if planted in the open ground, their stems, like those of other perennials, are killed down to the ground in winter; but the aggregated roots survive with but a very slight protection, whence the flowering stems of the next summer are produced.

There are various methods of cultivating the chrysanthemum. The easiest, perhaps, is to plant them close under a wall, to which the stems are trained during their growth. They may also be planted singly in the flower borders, and the shoots kept tied to a stake as they advance in height. But, as the plants flower very late in the season, a circumstance for which they are much prized, they require assistance from heat, either reflected from a wall, or applied in some other way, in order that the flowers may be sufficiently forward to blow before the frosts set in.

Young shoots separated from the old stool, or cuttings made of the earliest shoots, are soon established as individuals, and in this state grow much more luxuriantly than if they had been left on the parent stool. These young individuals, being more robust in habit, produce larger flowers, and these in greater abundance.

As the flowers are terminal, that is, produced on the points of the shoots, they cannot appear until the stem has gained its full height, which is sometimes, when trained to a wall, six or eight feet; and when allowed to grow so tall, and kept in pots, are very inconvenient in a greenhouse. To counteract this tendency to run up, and to have low bushy plants and a plentiful bloom, a judicious practice has been had recourse to by some florists with the best effect. This is by layering the strongest shoots, in the months of June and July, into pots of light rich compost, plunged in the ground at a proper distance round the stool, and in a shady place. The point of the layered shoot is thus furnished with a new system of active roots, which are competent to perfect the further elongation of the shoot, with its terminal bouquet of flowers; and these, though quite perfect as to form and colours, are never quite so large as would have been borne by the shoot if it had not been layered at all. Each stem bears a branched head of

flowers; and if a few only are wished to be as large as possible, they may be thinned by cutting off all the inferiors before they are too far advanced.

There are other ways of dwarfing the chrysanthemum besides layering them as above described. Starving them in poor sandy soil, in diminutive pots, and allowing but short supplies of water, will check luxuriance; but this is always at the expense of the beauty and size of the flowers.

CHRYSIDIDÆ (Leach). A family of hymenopterous insects, belonging to the section *Pupivora*, and distinguished, not only by the exceeding brilliancy of the colours of the insects of which it is composed (whence the origin of the name which signifies golden flies), but also by the antennæ having thirteen joints in both sexes, the basal joint being the longest, so as to form, at its extremity, an elbow with the remaining joints; the mandibles are narrow, curved, and pointed; the lower wings are destitute of nervures, and the abdomen of the females is terminated by an articulated retractile ovipositor, composed of several of the apical segments of the body, the abdomen itself appearing to be composed of only three or four segments. The under surface of this part of the body is concave; so then, when the insect is alarmed, it contracts itself into a ball, like a wood louse, leaving the wings only exposed. These insects are adorned with the richest colours, the thorax being generally of a fine blue colour, and the abdomen of a polished coppery flame colour; they fly, in the hottest sunshine, about old walls and palings exposed to the sun, with very great agility, seeking entrance into the burrows of other insects, in the nests of which they deposit their own eggs, in the manner of the cuckoo-bees. See *Cuculina*. M. St. Fargeau has observed the proceedings of the female of the species *Hedychrum regium*, which, in general, selects the nests of *Megachile muraria*, a wild mason bee. Having entered one of the nests of this bee, head foremost, it drew back and turned itself round for the purpose of introducing the hind part of its body into the nest, walking backwards. The bee, however, arrived at this critical juncture with a supply of pollen paste, no sooner, however, did she perceive her enemy than she pounced on it and seized it with her jaws; like the *Chrysididæ* in general, however, it immediately rolled itself into a ball, so that the jaws of the bee, although very powerful, were not able to affect the least wound upon the polished cuirass of the *Hedychrum*; she, however, cut off the four wings of the latter which were undefended, and then let it fall to the ground. She then visited her cell with some inquietude, deposited her store of provision, and returned to the fields for a further supply. No sooner, however, was she gone than the *Hedychrum*, which had, during the interval, remained rolled up, unrolled itself, erept up the wall, and quietly deposited its eggs in the cell, from which it had just previously been precipitated, placing them in the midst of the paste against the walls of the cell, which prevented the *Megachile* from perceiving it.

De Geer found the *Chrysis micans*, in the resinous gall of the pine, whence he surmised that its larva had been nourished upon the larva which had been previously inclosed therein, having observed at the bottom of the cell of the gall, an empty cocoon, composed of loose silk, which the *Chrysis* had pierced in order to make its escape.

This family comprises the genera *Parnopes*, *Chrysis*, *Stilbum*, *Euchærus*, *Pyria*, *Hedychrum*, *Elampus*, and

*Cleptes*. The genus *Chrysis* has the mandibles with one small tooth, the labium rounded and entire, the maxillary palpi much longer than the labial, and the thorax not narrowed in front.

There are about thirty-five species of this beautiful family found in this country, two-thirds of which belong to the last mentioned genus, of which the *Chrysis ignita* of Linnæus is the type.

**CHRYSHIPHALA** (Ker). A Peruvian family of bulbous herbs, introduced within the last fifteen years. Linnæan class and order, *Hexandria Monogynia*; natural order, *Amaryllidææ*. Generic character: perianth tubular, tube contracted in the middle, limb erect, and expanded like a funnel in six divisions; corolla shortened interiorly, toothed, and bearing the stamens; filaments awl-shaped and erect; anthers incumbent; style thickly spindle-shaped below; stigma club-shaped; capsule three-celled, three-valved, and many-seeded. This genus was called *Stenomison* by Herbert, and *Pancratium* by Ruiz and Pavon.

**CHRYSOBALANÆÆ**. The cocoa-plum family. A natural order of dicotyledonous plants, containing nine genera and upwards of thirty known species. By some botanists the order is considered as a section of *Rosacææ*, to which it is undoubtedly allied. It has also an obvious affinity to *Amygdalææ*, but differs in having irregular petals and stamens, and a style proceeding from the base of the ovary. By the former of these characters, as well as by the cohesion which exists between the ovary and the calyx, the order may be said to approach *Leguminosææ*, but the position of the styles and ovula, and the relation which the odd lobes of the calyx bear to the axis of inflorescence, are sufficient to distinguish the two orders.

The following are the botanical characters of *Chrysobalanææ*: calyx five-lobed; petals more or less irregular, either five or none; stamens definite or indefinite, irregular in size or position; ovary solitary, free, its stalk cohering on one side to the tube of the calyx; ovules two, erect; style single, arising from the base; stigma simple; fruit, a drupe one or two-celled; seeds usually solitary, erect; embryo with fleshy cotyledons, and no albumen.

The plants referred to this order are trees or shrubs, with simple alternate stipulate leaves, and flowers in racemes, panicles, or corymbæ. They grow in tropical countries, and are found chiefly in the warm regions of Africa and America. A few species are supposed to exist in Equinoctial Asia, and one is said to be found as far north as the pine-barrens of Georgia, in America. In the latter country, however, it is to be remarked, that the climate is much warmer than in most countries lying in the same parallel of latitude. The order furnishes some esculent fruits, but none of the plants appear to be possessed of any particular medicinal properties. The genera are, *Chrysobalanus*, *Moquilia*, *Corcepia*, *Acioa*, *Parinarium*, *Grangeria*, *Læcania*, *Thelyra*, and *Hirtella*.

*Chrysobalanus Icaco* is an irregular shrub, eight or ten feet high, which grows in South America and in the West Indies, in situations not far from the sea. It bears small whitish flowers, and yields a fruit the size of a plum, which is sometimes of a white, at other times of a yellow, red, or purple colour, and is eaten in the West Indies under the name of cocoa-plum. It has little odour, and a sweetish taste. The

root of the plant is astringent, and has been used as such medicinally. *Chrysobalanus luteus* resembles the lemon-tree, and is found in the maritime parts of Sierra Leone. It yields an esculent fruit the size of a plum, which is sold in the markets.

*Parinarium excelsum*, found on the mountains of Sierra Leone, supplies an insipid fruit, eaten by the negroes under the name of the rough-skinned or grey plum. The kernel of the fruit of *P. campestre* and *montanum* is said to be sweet and edible.

*Grangeria Bourbonia* is a tree the size of an oak, with entire leaves and small flowers, found on the Isle of Bourbon.

*Hirtella Americana*. A tree twenty-five feet high found in Cayenne and Guiana, is furnished with a reddish bark, and has its branches covered with fine hair. Some of the species of this genus are tall trees of the tropics, which support themselves on other plants.

**CHRYSOBALANUS** (Linnæus). This is a West Indian fruit tree, called the cocoa-plum. It belongs to the class *Icosandria Di Pentagynia*, and to the natural order *Rosacææ*.

**CHRYSOBERYL**. A very beautiful mineral, of a yellowish-green tint, which derives its name from a Greek word, indicative of its peculiar hue. It sometimes exhibits a milk-white opalescence, which appears in general to radiate from the interior of the mineral, and reflects much light. It is seldom found crystallised; but the primitive form is a prism of 104° 41'. The most frequent secondary forms are those

Fig. 1.

Fig. 2.

Chrysoberyl.

in the accompanying figures. Fig. 1, is a short and broad six-sided prism, or thick table; fig. 2, a very short and broad six-sided prism, acuminate on both ends with six planes, set on the lateral planes, and the orifices truncated.

This mineral occurs in Brazil, in alluvial soil with the topaz, or in sand-stone with the diamond. Some are also procured from the United States. The beds of the rivers in Ceylon occasionally present this mineral; it is there sometimes found in conjunction with sapphires, rubies, and tourmalines. The finest specimens of the chrysoberyl employed in this country for the purposes of the jeweller, are those imported from South America.

**CHRYSOCHLORIS**—Golden-green Mole. A genus of carnivorous mammalia, belonging to the division which feed on insects. The generic characters are: two incisive teeth in the upper jaw and four in the under, the cheek teeth stand high, are separate from each other, and have the form of triangular prisms. Their muzzle is short and turned up; their fore feet have only three claws, of which the exterior one is

very large, pointed, and crooked, and serves them for digging their way rapidly under ground; the hind feet have five claws on each, which are of moderate size. Their habits are similar to those of the common mole; but their organisation is very different. The clavicle is much more slender than in the mole, while the first rib is on the contrary much thicker and very long. The blade bone is also large, and the humerus is nearly three times the length of that of the mole. The fore arm is also supported by an additional bone. Indeed there is no animal in which the shoulder is better articulated for powerful motion than in this genus, small as are the animals. There is but one species which is well established, the golden mole of Southern Africa (*C. Capensis*), but this one has occasioned no small trouble to those naturalists who make colour a principal character, and describe animals from museum specimens.

This species is a very small animal, considerably less than the common mole of Europe; in consequence of its subterranean habits it is not very frequently seen; and in respect of colour it is as perplexing as the camelion. We believe that the real colour, that is the colour as seen in light which is not refracted, is brown; but, different from all other mammalia, this small animal has the same metallic reflections in its fur which are observable in the feathers of many birds, the range of these colours being from a deep golden yellow, or rather a sort of bronze red, to a bronze green; and as all animals which have the metallic reflections lose them when dead and dried, the stuffed skin of this one conveys no idea of what the living animal is like. Hence it has been described as if of different colours, and has been attributed to different parts of the world, as to America and Siberia. There are many districts of these parts of the world which are still very imperfectly known, and the habits of those small burrowing mammalia render it very difficult to ascertain what are their numbers; and therefore the subject is one upon which mistakes are unavoidable, as there may be many species in those unexplored countries of which no individual has been seen. This animal has no apparent tail, no external concha to its ears, and no visible eyes, until they are forced open by direct experiment. Its snout is formed with a moveable cartilaginous rim, and by means of this and its powerful fore-paws it gets along the ground with considerable celerity. In Southern Africa it is nearly as troublesome in rooting up gardens with its subterranean passages as the common mole is with us. Its time and manner of breeding, and its general habits, farther than that it is a dweller in the earth, are little known; but it is ascertained that the female has two mammæ situated in the groin.

This species has sometimes been confounded with those animals which are properly styled rat-moles on account of their having the habits of moles, at least in so far as burrowing is concerned, while they are rodent or gnawing animals in their general structure. Those which have this compound character may be considered as in so far omnivorous, eating indiscriminately small animals and succulent vegetable matter, whereas the cheek teeth of this genus are wholly or chiefly of an insectivorous character; and therefore it only disfigures those grounds in which it makes its runs, and does not eat the fibres of vegetable roots. Though a small and obscure animal, this is remarkable for its beauty, if it were possible to preserve that beauty in the dried skin. Its colours have already

been mentioned, and we may add that the texture of its fur is more delicately soft, and also more beautiful in its lustre than that of the mole. It is worthy of remark, that these small burrowing animals are neither soiled by mud nor readily wetted by water.

**CHRYSOCOLLA.** A genus of molluscs established by De Montfort, but united with the genus *Polystomella*, of which it forms one of the divisions.

**CHRYSOCOMA** (Linnæus). A genus of yellow flowering shrubs from the Cape of Good Hope, and herbs, natives of Europe and North America. These plants are the goldlocks of our gardens, and belong to the natural order *Compositæ*, propagated by cuttings and division of the root.

**CHRYSOLITE.** This mineral is characterised by its pistachio green colour. It is brought to Europe from the Levant, and is said to occur in upper Egypt, on the shores of the Red Sea, and in the Isle of Bourbon. The chrysolite has a considerable degree of lustre and transparency; but it is one of the softest of the precious stones, hence jewels of it become dull on the surface, if the slightest attrition be employed.

**CHRYSOMELIDÆ** (Leach). A very extensive family of coleopterous insects, belonging to the section *Tetramera*, and sub-section *Cyclica* of Latreille, which latter group is almost identical with the Linnean genus *Chrysomela*, but which, from the amazing number of additions made thereto since the days of the great Swede, it has been considered necessary to separate into three divisions, namely, the *Galerucidæ* (*Galerucitæ*, Latreille); *Chrysomelidæ* (*Chrysomelines*, Latreille); and *Cassididæ* (*Cassidaridæ*, Latreille. See *CASSIDA*). These groups are conjointly characterised by having the body of a small or but moderate size, and of an oval or rounded form, being seldom elongated. The antennæ are seldom so long as the body, and filiform or gradually thickened towards the tips; the thorax is sometimes as wide behind as the base of the elytra; the three basal joints of the tarsi are dilated and spongy beneath, forming a kind of cushion; the legs are of a moderate length, but rather thickened, especially in the part termed the femur or thigh, which in the hind legs is sometimes greatly incrassated, as in the turnip beetles (*Halticæ*) and some others. Generally speaking, these insects are of sluggish habits, frequenting plants and vegetables, upon the leaves of which they feed both in the perfect and larva state; being during the latter period of their lives of a soft fleshy consistence, with six legs, and emitting a viscid secretion, which serves to affix them to the objects upon which they are placed. It is here also they are transformed into pupæ, the posterior part of the body being affixed to the leaves, &c., and surrounded by the cast skin of the larva. In both these preparatory stages, the body of the insect is ornamented with various colours, and in the perfect state we find nearly the whole group distinguished by their highly polished and metallic tints, whence the origin of their name, which signifies golden beetles. When disturbed, they immediately fall to the ground, folding their legs and antennæ along the sides of the body. It is, however, in tropical climates, where vegetation reaches its greatest luxuriance, that these herbivorous insects abound; and to so great an extent, that from the state of our collections, we should feel inclined to average the Linnean *chrysomelæ* at, at least, one-eighth of the whole order of beetles.

Latreille has arranged the groups of which this division (*Cyclica*) is composed, from a consideration of the various habits of the larvæ, as follows:—1st, those which cover themselves with their own excrements (*Cassidæ*). 2nd, those which reside in portable cases (*Clythra*, &c.). 3rd, naked larvæ. 4th, larvæ living in the interior of leaves, feeding upon the parenchyma (*Halticæ*): but it is to be borne in mind, that this mode of distribution must be cautiously regarded, since the *Galerucidæ*, to which the *Halticæ* are referable, are naked, and it is by no means decided that the larvæ of the latter are internal feeders.

The three divisions or families above mentioned, may be readily distinguished by the following characters:—

1. *Cassididæ*. Antennæ arising close together, concealed at the base by the thorax.

2. *Chrysomelidæ*. Antennæ remote from each other at the base.

3. *Galerucidæ*. Antennæ close together at the base, and not concealed by the thorax.

The family *Chrysomelidæ* have the body oval, more or less tending to a globular or an oblong shape; the antennæ are generally slightly thickened towards the tips, and the legs are nearly of an equal size. These beetles, notwithstanding their small or but moderate size, are amongst the most beautiful of coleopterous insects; they are highly polished, and their colours are greatly variegated, green and gold, blue, purple, and crimson, being very conspicuous in the majority. Some of the species are social, as that found upon the leaves of the willow (*C. vitellinæ*), the larvæ of which feed in regular rows along the leaves. These larvæ have the body thick and fleshy, and terminated by a fleshy tubercle, which is employed as an additional seventh leg. The larvæ of one of the largest British species (*C. populi*), emits a disagreeable scent, a yellow oily fluid being discharged from the limbs when the insect is disturbed. Some of the larvæ undergo their transformations under ground. The pupæ, which does not present any peculiar characters, is of an oval form, and affixed by its posterior extremity to the leaves, the perfect insect making its appearance at the end of several weeks, or occasionally in a few days.

The family comprises two very distinct sections. 1st. Those having the head but slightly deflexed and exposed to view, the antennæ seldom exceeding half the length of the body, and slightly thickened to the tips, with the body of an oval form. Here belong the genera *Phædon*, *Melasoma*, *Chrysomela*, *Helodes*, and *Timarcha*, all of which are British; and *Colaspis*, *Podontia*, *Phyllocharris*, *Doryphora*, *Paropsis*, *Trochalonota*, *Cyrtonus*, which are exotic.

The genus *Chrysomela*, as restricted in the latest works, is distinguished by having the palpi somewhat hatchet-shaped, the thorax transverse, the elytra separated, and the body furnished with wings. The tibiae also have a tooth or tubercle on the outside near the extremity, fringed with hairs. There are nearly thirty British species of this elegant genus, of which the *Chrysomela sanguinolenta* of Linnaeus is one of the most common examples; it is about one-third of an inch long, of a blue-black colour, with the elytra widely margined with red.

The second section of this family comprises those species which have the head vertically immersed into the frontal cavity of the thorax, so that the body forms a kind of thickened cylinder, having the anterior part

cut off perpendicularly. The antennæ in the majority are almost as long as the body, and slender to the tips. Here belong the genera *Cryptocephalus*, *Eumolpus*, *Colaspis*, and *Clythra*, all of which are British, together with *Chilanyx*, *Lamprosoma* and *Euryope*, exotic genera. The second genus comprises the *Eumolpus vitis*, Fabricius, a species which has become distinguished by its ravages upon the vines in the wine countries of Europe; its larva appearing in the spring, and devouring the leaves of this plant, as well as the young buds, as soon as they appear on the stems; it also gnaws the footstalk of the bunch of grapes as soon as it is exposed, causing it to droop and die; sometimes however the shoot is sufficiently strong to survive the injury, but the grapes in these bunches are of small size on that part which corresponds with the injury, in consequence of their receiving but a small portion of sap. The perfect insect is of a black colour, and pubescent, with the elytra, the base of the antennæ and tibiae, of a reddish-brown. The genus *Clythra* has the antennæ very short and serrated; the larvæ reside in tubular cases, of a leather-like texture, which they bear about with them. There are several British species.

**CHRY SOPHRIS.** A genus of spinous-finned fishes, belonging to the gilt-head family *SPARIDÆ*, under which some notice of the genera composing that family will be found.

**CHRY SOPHYLLUM** (Linnaeus). West Indian fruit trees of large size, yielding useful fruit called the star apple. Linnaean class and order *Pentandria Monogynia*; natural order *Sapotææ*. Generic character: calyx five parted; corolla bell-shaped and rotate; limb divided into five spreading petals; stamens inserted in the tube of the corolla; stigma almost sitting, peltate, and of ten lobes; fruit, a round apple of from five to ten cells, each containing one seed covered with a bony shell. The foliage of these trees is beautiful, for which they have a place in our hot-houses; but they never arrive at that amplitude to produce their fruit. They are increased by cuttings like other stove plants.

**CHRY SOSPLENIUM** (Linnaeus). A genus of three species of plants, two of them British, and frequently found on wet boggy ground, and known by the trivial name of golden saxifrage. They belong to the tenth class of Linnaeus, and to the natural order *Saxifragææ*.

**CHRY SOTOSUS.** A genus of spinous fishes, belonging to the mackerel family, of which the characters are: a total absence of teeth, a single dorsal fin furnished with spines, the body compressed, the scales remarkably small, and the eyes placed laterally, with the exception of the coryphænes to which they are nearly allied, this genus is one of the most beautiful that inhabits the ocean. There is one species which is occasionally met with in our seas, though it is a ranging fish, and therefore is but rarely caught. When a specimen is met with, its beauty draws a considerable degree of attention, and therefore it has had many names bestowed upon it. It is the ophah of Pennant, the *Zeus imperialis* of Shaw, and the moon-fish of other writers. It is a fish of considerable size, and so much compressed, that when seen laterally its figure is nearly round. Its caudal fin is white, and very much forked; its dorsal fin is very elevated and sithe-shaped; its ventral fins are very long; and all the fins excepting the caudal are bright red. The ground colour of the body is a beautiful violet,

marked with white spots; but the colours vary a good deal with the light in which the fish is seen. The back, as turned away from the light, appears a beautiful blue with silvery spots, while the rest of the body reflects an endless variety of brilliant colours. Its habits, further than that it is a very discursive fish, are very little known, and we believe not more than a single specimen has been met with at one time.

**CHTHAMALUS** (Ranzani). The shells of this genus are extremely flat; the coronary part with its sides much thicker at their base and formed of six pieces, as in the *Balani*, areas nearly equal; the internal division short, a membranous stem or support; the opening tetragonal, with nearly equal sides, surrounded by a membrane to which is attached horizontally, an operculum, composed of four pieces, slightly pyramidal. Only two species are known of this shell; they inhabit the Mediterranean sea, and are classed in the family *Balanidea*. They appear an intermediate genus between the *Balanides* with pyramidal opercula, and those with horizontal opercula.

**CIBICIDES** (De Blainville). A species of shell of which only one species has yet been described. The *C. refulgens*, nevertheless, is so strongly characterised, that it merits the rank of being considered a genus. Shell trochoide, very much flattened, and umbilicated with the chambers visible and radiating from the centre on one side, conical but not spiral on the other; the aperture linear, through the height of that side. 1st class *Cephalophora*; 3rd order *Polythalamacea*; 6th family *Turbinacea*.

**CICADA** (Linnæus; *Cicadaria*, Latreille). A group of insects, which, in the Linnæan system, formed the genus *Cicada*, but which, from the great increase in the number of the species, and the great variations in structure which they exhibit, has been formed, by modern entomologists, into several distinct families, each consisting of numerous genera. They are characterised as a division of the order *Hemiptera*, and sub-order *Homopterita* (Kirby), by the minute size of the antennæ, which are of a conical form and terminated generally by a fine bristle, and these organs have never more than six or seven joints; the tarsi have only three joints; the wings are concealed by a pair of hemelytra or wing covers which, however, during flight, perform the offices of wings, being of a similar consistence throughout their whole extent, in which respect they differ from the *Cimicidæ* or bug tribes, in which the wing-covers are composed of two distinct kinds of membrane, or rather of corium and membrane; the proboscis, which is employed in wounding and sucking the juices of plants, arises from the under side of the head, near the fore legs; the hind legs are adapted for leaping; and the females are furnished with an apparatus well fitted for depositing their eggs, being composed of two saw-like organs, somewhat similar to those of the true saw-flies, *Tenthredinidæ*.

These insects, which from their saltatorial powers have acquired the name of tree-hoppers, are amongst the most celebrated of the lower animals. They were known to the Greeks, who were accustomed to keep them in cages for the sake of their song, under the name of *Tetrix*, and they form a favourite theme in the verses of every Grecian bard from Homer to Anacreon. "Sweet prophet of the summer," says the latter, addressing one of these insects, "the muses love thee, Phœbus loves thee, and has given

thee a shrill song, old age does not wear thee out, thou art wise, earth-born, musical, impassive, without blood, thou art almost like a god!" The hieroglyphics of Egypt, in like manner, give evidence of the attention with which these insects had been observed; and in which, from their organs of sound, which were supposed to be placed upon the back and not at the mouth, they were emblematically represented as the ministers of religion. Aristotle, who named these insects *Tetrix*, says that that they have no mouth, but a kind of tongue placed beneath the breast, and serving to suck up the dew. He likewise distinguishes two kinds of *tetrix*, the larger which sing, which he calls "achetes," and the smaller, which are silent "tettigion or tettigonia;" *cicadrasæ* in Latin. The eyes were supposed to be very weak, for Pliny adds, that if the finger be placed close to them, they will creep upon it as though it were a leaf; this however is certainly incorrect, for it is well known that when they are approached, they use both their wings in flying and legs in leaping, in order to get out of harm's way. The female, says Pliny, is provided with a pointed instrument or auger, which pierces the earth, reeds, stems of the vine, &c., when the insect wishes to deposit her eggs. The pupæ of these insects have very little the appearance of the perfect flies; the body is thick and heavy, and the fore legs very large, with the anterior thighs greatly incrassated and toothed. They were called by the Greeks *Tettigometræ*, or the mother of the cicadæ. Diodorus informs us that these insects do not exist in the district of Locres, because Hercules, annoyed by their chirping, prayed the gods to deliver the country from their noise, whereupon his prayers were heard. Several Eastern nations eat these insects; the males before coupling, and the females after impregnation, are most relished. Isidore of Seville, doubtless misled by the frothy matter in which the larva of the *Cicada* (*aphrophora*) *spumaria* is found, says that the *Cigales* or *cicadæ* spring from the saliva of the cuckoo. "Cuculorum nascuntur sputo," Orig. lib. xxii. cap. 8. The organs by which the chirping of the cicadæ is produced, have been well described by Reaumur. They are placed on the under side of the body, between the base of the hind legs and the abdomen, and consist externally of a pair of large flattened plates of a horny texture, varying in form in the different species. When raised, they are found to conceal a large cavity partially covered with membrane of a much more delicate nature than the external covering, with a horny plate in the middle, placed horizontally along the bottom; the sound is, however, produced by a bundle of muscles still more internally, and when these strings are pulled and suddenly let go, even in a dead specimen, the sound is produced as well as though the insect were still alive, the sound issuing through an opening contrived on purpose, somewhat analogous to the sound hole of a violin. It is to be observed however, that it is only the male insects which are provided with this apparatus, the opposite sex being destitute thereof, and consequently silent; hence the couplet of the Rhodian bard, Xenarchus, not over-famed for his gallantry to the fair sex,

Happy the cicada lives  
Since they all have voiceless wives.

Great diversity of opinion has been entertained of the music of the *tetrix* or *cicada*; this however may

perhaps be accounted for, from the circumstance of several distinct species having been comprehended under the same name, varying in their powers of song: thus a cicada sitting upon a harp was the usual emblem of music, which appears to have had its rise from the following legend. Two rival musicians contending upon the harp, a cicada settled upon the instrument of one of the artists, and supplied the place of a broken string, and so secured him the victory; and in Surinam these insects are also called harpers or lyre-men. By others, however, they have been held in less estimation; thus Virgil tells us that they burst the very shrubs with their noise. Some of our translators have indeed adopted the very common error, that they were insects of a very different family. Thus Dryden (Georgic iii. p. 510) sings—

When creaking grasshoppers on shrubs complain.

although from Virgil's words

Et cantu querelæ rumpent arbusta Cicadae,  
Georgic iii. p. 328,

it is evident that the insects now under consideration were alluded to. In like manner Dr. Shaw tells us, that the "cicada is perpetually dunning our ears with its most excessively shrill and ungrateful noise."

The curious apparatus with which the females are provided, for enabling them to make slits in the branches of trees for the purpose of depositing their eggs therein, has somewhat the appearance of two long narrow files, pointed at the end, moving with a separate or alternate motion, and supported by a broader back entire piece. This apparatus in the larger species is about half an inch long, and is ordinarily concealed within the terminal rings of the abdomen on its lower surface. The situations upon the twigs on which the eggs are placed, are easily recognised by the little inequalities upon the surface, placed one after the other. Each hole contains from five to eight eggs.

The preceding observations have reference to that portion of the Linnæan genus which were termed *Mannifera*, and comprises the modern family *Cicadidæ*. The divisions established at the expense of the former group (together with that of the Linnæan *Fulgoræ*, which are so intimately allied to the former, that some of the Linnæan cicadæ are now placed in the family of which *Fulgora* is the type) are as follows: 1st, the *Cicadidæ*, having the antennæ six or seven-jointed, and the ocelli three in number. This family corresponds with the genus *Tettigonia* of Fabricius, and comprises only a single genus, for which the Linnæan name cicada has been retained. Latreille, in several of his recent works, proposed several other generic divisions, but they have not been adopted. We possess in England only one species belonging to this family, which has been supposed to be the *C. hæmatodes*, but which Mr. Curtis has figured under the name of *C. Anglica*. It is met with in the New Forest. 2nd, the *Fulgoridæ*, having the antennæ three-jointed, and inserted close beneath the eyes, with a long terminal bristle; two ocelli; legs formed for leaping; no musical drums; the head is often produced in front into a nose. See *FULGORIDÆ*. 3rd, the *Cercopidæ*, having the antennæ of similar form as in the second family, but inserted between the eyes and the head, which is not rostrated. See *CERCOPIDÆ*.

CICHORACEÆ. See COMPOSITÆ.

CICHORIUM (Linnæus), is the succory of

English authors; a common plant, found by the sides of fields and highways, and is sometimes cultivated for sheep food. It has large bright blue flowers,—belongs to the class *Syngenesia* of Linnæus, and to the natural order *Compositæ*. There are several annual species, one of which, a native of India, is the well known salad plant called *Endive* (for the cultivation of which see *ENDIVE*), long cultivated in gardens everywhere. In some places on the continent of Europe, the roots of the succory *C. intybus*, are, when full grown, taken up, cut in small pieces, dried in an oven, and afterwards ground and used instead of coffee.

CICINDELIDÆ (Leach). A family of coleopterous insects, belonging to the section *Pentamera* and tribe *Adephaga* (*Geodephaga*, see *CARABIDÆ*) being placed by modern authors at the head of the *Coleoptera*, from the circumstance of the external lobe of the maxillæ being converted into an additional pair of feelers, forming the internal maxillary palpi. The jaws are very powerful and horny, with several strong teeth; the maxillæ are terminated by a moveable spur; the lower lip is hidden by the chin, and the eyes are very large and prominent; the legs long and slender, and the wings generally developed.

This family comprises nearly twenty genera, one only of which is found in England, namely, *Cicindela*, the remainder being in fact extra European, and consequently very little being known respecting their habits. Of these insects, which, from their ferocious habits, as well as from the spots and markings with which they are ornamented, have obtained the name of tiger beetles, there are only six or seven British species, although the genus comprises more than one hundred and twenty. Of these British species the most common is the *C. campestris*, an elegant insect, having the body of a fine green colour, with several white spots on the wing covers. Nothing can exceed the metallic brilliancy exhibited by these insects, when on the wing in the hot sunshine. They appear early in the spring (we have seen them flying this morning, April 8th, in the Horticultural Gardens); on approaching them they immediately take wing, exposing the upper surface of the abdomen, which is highly polished, and ornamented with the most beautiful colours. Their flight is however but of short duration; they, however, rise again immediately as you again approach them. The great rapidity of their motions, renders escape impossible to any luckless insect which they may attack. We have noticed that this insect emits a fine rose-like scent. Some of the species seem to make but little use of their wings, as in the British species, *C. Germanica*. The female of the *C. campestris* is distinguished by a small black spot on each elytron, not far from the base, and near to the sutural line.

The most complete account hitherto published relative to the transformations of these insects, is contained in the *Annales des Sciences Naturelles*. The larvæ reside in cylindric burrows of great depth, which they excavate in sandy situations, at the mouth of which they generally station themselves, the head of the larva occupying the mouth of the burrow. They are about an inch long, rather depressed and narrow, composed of twelve rings exclusive of the head, and the anal segment. The head is furnished, like the perfect insect, with a pair of very powerful hooked jaws; the legs are six in number, and comparatively strong. The reader will smile with us at

the following account given of one of these larvæ, described by Dr. Kidd "with an eye to science." "Oh such a beauty! the Parcæ, sweet creatures, the Eumenides, gentle turtle doves, were lovely in comparison. Aspect vicious; temper ferocious; eyes infernal; jaws diabolical, stuck on the wrong way like a figure-head shipped looking aft; head big; back humped; the hump adorned with two hooks."—Rusticus, in Ent. Mag. The description given of the jaws is correct, and affords a curious instance of adaptation of means to an end, of which insects exhibit such numberless examples. One cannot at first but wonder what can be the cause of these jaws being so singularly stuck on the head, being in fact turned upwards, instead of downwards as is the ordinary custom in insects; but when we consider the habits of the insect in conjunction with the peculiarities of its structure, our wonder ceases; the insect takes its station at the mouth of a cylindrical burrow, in the hope of seizing upon the stray beetles and flies; now if the jaws were in the ordinary position, the insect would be compelled to throw back its head to a distance beyond its powers, were it to attempt to snap at its prey when creeping over or near the mouth of the burrow; but as the jaws are placed, it is enabled to effect this without the least difficulty. The two hooks upon the back of the eighth segment of the body are also especially worthy of notice, as it is by their assistance that the insect climbs up and retains its situation at the mouth of its cell. The amusing author above quoted turned up one of these larvæ, in order to watch its proceedings. "When first unearthed he was monstrous sulky, and lay twisted in a kind of half kink, for all the world like a pot-hook; but he soon found the inconvenience of this, and set to work to make another hole, for which he used his feet and jaws, loosening the sand with his feet, and fetching it out with his jaws," (he might have added that the back of the head being rather concave, is employed as a basket for carrying up the loosened particles); "in this way he got down about half an inch, and then adroitly hanging himself to the edge of the hole by the hook (hooks) in his back, he continued his labours in this droll position; at last he got quite out of sight, and as he did not come up again, I concluded he was taking a nap after his labour, and so I would not again disturb him." The perfect insects are very common in most sandy districts. They abound in the neighbourhood of London, and the circular orifices of their burrows may be seen in all directions, on the sunny sides of gravel pits, &c.

**CICONIA**—**STORK.** A genus of birds belonging to the *Cultrirostral* division of Cuvier's order of *Echassiers*, which answers nearly to the *Grallæ* of other naturalists; for the relations see the article **BIRD**.

The storks are a very interesting race, whether we regard their size or their habits; and in those countries where the rains are periodical, much of the country laid under water for a time, and numerous animals remain left by the subsiding waters, which would taint the air if they remained and were decomposed there, they perform a very important office in the general economy of nature. They are all more or less migratory, and, with the exception of the colder latitudes, are found on the low grounds in almost every part of the world, though the true storks are mostly confined to the eastern continent.

The characters are: bill long, straight, stout, even, cylindrical, in the form of a lengthened cone, acute, cutting ridge, rounded, of equal height with the head; the under mandible slightly bent up; nostrils longitudinally cleft in the horny substance, and placed in a groove; eyes surrounded with a naked space which does not communicate with the beak; legs long, and furnished with four toes, of which the three anterior are connected at the base by a membrane, and the hind has its first joint resting on the ground; wings of moderate size.

Storks live in marshy situations, and feed principally on reptiles, frogs and their spawn, as well as on fish, small mammiferous animals, and birds. In many countries they are a privileged race, being cherished and protected, on account of the noxious animals which they destroy. They moult in autumn, migrate in large bodies, and are easily tamed. The young of the first year do not very materially differ in appearance from the full grown birds; but they may still be recognised, on their return in spring, by the dull black and white of their plumage. The sexes are not dissimilar in appearance.

Storks have no voice, properly so called, though when they are irritated, or otherwise strongly excited, they contrive to make a clanking noise, by beating the edges of their mandibles, which are very hard and strong, against each other; when they do this they place the head in rather a singular position; they recurve it backwards, until it is nearly parallel with the back, and leaning on it. In this position the upper mandible is undermost, and held firm by the posture of the neck, while the under, which is now uppermost, beats much more easily and forcibly against the other than if the bill were in its natural position, as in this case the weight of the mandible aids the stroke, while it acts against it in the other. It does not appear that the muscles which move the under mandible, strong as they are, would be capable of performing this singular sort of cymbal playing, if the weight of the organ were not brought to their assistance; for as the bird brings its head back to the natural position, the sound gets lower, and when it snaps with the bill in the natural way, no sound is produced.

Storks are birds of long flight and powerful wing, and they rise high and proceed gracefully upon their long aerial journeys; on the ground their march is rather slow but stately, their steps being long and measured. As is the case with most birds of the order, they carry the foot forward simultaneously with the leg, and this sort of locomotion is owing to a peculiar system of articulation. To the same mechanism the storks are indebted for the faculty of sleeping upon one leg, holding the other bent, and often even suspended rectilinearly. The pleasant story told by Boccaccio, of the gentleman and his cook, affords an agreeable illustration of this habit of the stork: a roasted stork had been ordered for dinner, and the legs of this bird being the most substantial as well as the most juicy parts of it, the master was of course anxious to have them for his own use. But there was another claimant: the cook had a sweetheart, and she was so urgent for a leg of this stork that the gallant cook was constrained to cut it off and give it her; when the mutilated stork made its appearance on the table, the master, in a great rage, sent for the cook, and charged him with having purloined the leg. "Storks have but one leg, sir," said the cook with the ut-

most composure; "and if you will condescend to repair with me to the bank of the river to-morrow morning, I will convince you of the fact." Morning came, the river was visted, and sure enough there was a number of storks, all of which appeared to have but one leg. "There they are, sir," said the cook, "and you see there are no more legs than storks." "Hoo!" said the master, upon which every stork displayed his other leg. "Now," said the master, "have not I convinced you what a cheat you are?" "I beg your pardon, sir," said the cook, "not one of these storks put down his other leg till you cried 'hoo,' and of course if you had cried 'hoo' to the stork yesterday, he would have put down his other leg too." We shall now give some account of some of the principal species.

**WHITE STORK** (*Ciconia alba*). White, with the orbits naked and crimson; quills and upper tail-coverts dusky green. The irides are brown; and the feathers on the breast long and pendulous. Length about three feet and a half; extent of wing upwards of six feet; size about that of a turkey. The young have the black of the wings tinged with brown, and the bill of a dusky red. A pure white variety, called *Sterchi* by the Bulgarians, is found in the valley of the lower Danube.

From the familiarity of their disposition, and its other moral habits, the stork is one of the most popular of littoral birds, and has been generally regarded as the friend of man, attached to his dwellings, nestling on roofs and chimneys, catering on the banks of the most frequented rivers, in cultivated fields, and almost in gardens, not even shrinking from the bustle of crowded cities, taking up its abode in towers, and everywhere respected and welcomed. In Holland it is protected, because it checks the multiplication of reptiles in the marshes and humid flats; the Vaudois cherish and venerate it for its friendly offices; the Arabs, in like manner, treat it with the most hospitable regard; and the Turks and eastern tribes consider it as a sacred bird, which they are forbidden to kill. At Constantinople, accordingly, the storks build their nests in the streets; but in other countries they generally prefer a lofty situation. A mussulman cannot patiently bear to see one of them molested; and the ancient Thessalians made the killing of them a capital crime. The Moors, too, religiously abstain from offering violence to them; and hence the valley of Monkazem appears to be the resort of all the storks of Barbary, which, in this district, are more numerous than the inhabitants.

The white stork is of gentle manners, easily tamed, and manifests a sense of cleanliness. Although it has a pensive and even melancholy air, it occasionally indulges in gaiety and pastime, associating even with children, and partaking of their amusements. "I saw in a garden," says Dr. Hermann, "in which the children were playing at hide and seek, a tame stork join the party, run its turn when touched, and distinguish the child who was to pursue the rest so well as, along with the others, to be on its guard." Among the engaging attributes of these birds have been justly reckoned gratitude, conjugal fidelity, and filial and parental affection. They seem in fact to be very sensible of kind treatment saluting, with a noisy flapping of their wings, the houses whose inmates had given them a friendly reception during the preceding season, and repeating the same ceremony on taking leave. With wonderful constancy the same pair

return to the same haunts, and join in mutual and fond caresses after their long voyage. The tender affection which the stork manifests towards her young, has been proverbial even from remote antiquity. She feeds them for a considerable period, nor quits them till they are strong enough to defend themselves, and to provide for their own subsistence. When they begin to flutter about the nest, she bears them on her wings, and protects them from danger; and she has been known rather to perish along with them than abandon them to their fate, an affecting instance of which was exhibited in the town of Delft, in 1636, when a fire broke out in a house that had a stork's nest on it, containing young that were then unable to fly. The old stork, returning with some meat for them, and seeing the danger in which they were exposed, the fire having almost reached the nest, made several attempts to save them, but, finding all in vain, she at last spread her wings over them, and in that endearing attitude expired with them in the flames. Young storks have also often been observed to lavish the most affectionate and assiduous cares on their aged and infirm parents; and the ancient Greeks, observant of this striking instinct, enacted a law to compel children to support the authors of their existence, and the guardians of their infant years.

The stork is capable of sustaining a lofty flight, and of performing long journeys even in tempestuous weather. When on wing it pushes its head straight forward, with the feet extended backward. It returns to Alsace about the end of February, to Switzerland in the course of March, and to Germany early in May, but it rarely visits this country. If a pair on their return find their former nest deranged or demolished, they repair it with sticks, rushes, and other plants that grow in moist situations. It is usually placed on high roofs, the battlements of towers, and sometimes on the tops of tall trees, on the brinks of streams, or on the projection of a precipitous rock. In France it was formerly customary to lay wheels on the roofs of houses to induce them to build on them, a practice which still exists in some places. In Holland boxes are placed on the roofs of houses for the same purpose. The hatch consists of two, three, or four eggs of a yellowish sordid white, larger than those of the goose, but not so thick. The male sits on them while the female is abroad for food. The young make their appearance in the course of a month, when the parents diligently search for and carry to them the proper aliment, which they disgorge from their gullet or stomach. Both parents never leave the young at the same time, but while the one is ranging in quest of food, the other keeps watch, standing on one leg in the manner above described, and with its eye steadily fixed on its charge. When the young first break the shell, they are covered with brownish down; and their legs are so weak that they are not able to move in the nest in any other way than by shuffling about upon their knees. When their wings begin to acquire strength, their mothers accompany them in easy flights, though it is rather too much to assert, as is sometimes done, that they literally *teach* them to fly. There is no teaching, in the ordinary sense of the word, among animals of any kind, either in motion or in voice. The supposed teaching in walking or flight is merely the old ones keeping company instinctively with the young; and the teaching of music is simply rivalry in that impulse which occasions the song.

In some places storks nestle very thickly together, but they always live in the greatest harmony. At Bagdad there are hundreds of nests, on the houses, the walls, and the trees; and among the ruins of Persepolis, there is a stork's nest on the top of every nodding fragment and mouldering column.

About the month of August they begin to move from their more northerly haunts; and they move sooner in moist and cold seasons than in dry and warm ones. Previous to their departure they assemble in very numerous flocks upon some plain, and hold a conversation in that peculiar clanking of their bills of which we have taken notice. The motion of the mandible while this is performing is very rapid, and the clattering which they make is considerable. Sometimes they meet, break up, and meet again, before they take their final departure. When they do move off, it is done in perfect silence, and often during the night; and they also arrive in silence, so that neither the beginning nor the end of their journeys is often noticed. They rise rapidly to a great height, and as they utter no sound when on the wing, they are seldom observed when passing over the plains. But on the mountains they are more easily seen; and the flocks of them which are observed from such points of view are often very numerous. Shaw, the traveller, mentions having seen flights of them passing over Mount Carmel in their flight northward from Egypt, a mile in breadth, and taking three hours before they all passed over the point of observation. In Asia and the east of Europe they are very numerous, ranging into Siberia, into Russia, and even into Sweden; and they do not seem to be much affected by the cold. Those which breed in the north, in the early part of the season, generally have another brood in Egypt and the other southern countries; but they do not all quit these southern latitudes; and some of them are stationary in the east of Asia, and in some of the Asiatic islands, as well as in the north of Africa. In all their characters and habits they are very interesting birds; they may be said to be almost tame in a state of nature; and they live in confinement without any apparent inconvenience, or even much reluctance; but confinement is obviously contrary to their habits, as they do not breed in that state, and whenever animals cease to obey this, the strongest impulse of nature, we may safely conclude that the state is not one for which nature designed them. It is also worthy of remark, that, generally speaking, these animals, which will not breed in confinement, and therefore cannot properly be domesticated, are never of so much use to man as those which breed freely. Notwithstanding the tale of Boccaccio, the stork is very far from being a *bonny hawke*, even to the most perverted epicure; for its flesh is not very nutritious, and it is at the same time far from being savoury; therefore, there is but little temptation for taking the bird out of that state of nature in which it has so many interesting points.

**THE BLACK STORK** (*Ciconia nigra*). The black stork measures about three feet in length. The upper part is blackish, with metallic reflections; and the lower part of the breast and the belly white. The naked space round the eyes, and that on the neck, and also the bill, are crimson: and the feet are deep red. The colours of the young are different, the upper part being blackish-brown, with reflections; the feathers on the head and neck brown, with red-

dish borders; and the naked skin round the eyes and on the neck, and also the feet, are olive green. In consequence of this difference of colour, the young birds have sometimes been described as a different species, under the name of the brown stork.

Though these two birds agree in their general characters, the habits of the black one are, in many respects, the reverse of the white. Like that it is a ranging and migrant kind; but, instead of resorting to towns and inhabited places, it seeks those which are lonely and sequestered. Its haunts are the remote and inaccessible marshes, and the borders of lakes which are seldom visited. It is found in considerable numbers in the more sequestered parts of the Alps, always on the borders of the waters, where it subsists, at least in part, by fishing. It hovers over the surface, and occasionally plunges down to snatch its prey. It occurs in Poland and Prussia, and partially in Germany, also in some parts of France; but it is very rare in Holland where the white species is very plentiful. Indeed it seems to shun not only the peculiar haunts, but the countries which are most frequented by its congener. In Britain it has occurred only as a very rare straggler.

It builds in trees, in the depth of the forests; and, as is the case with several others of the larger birds of this division of the order, it appears to prefer fruit to any other trees, no doubt because it can stand on the horizontal branches which these send out, much better than on the sprays of deciduous trees. The eggs are from two to four, of a dull greenish white, with some blotches of brown, which do not appear to be constant. Though these birds sometimes fish, fishing is not their peculiar, or even their principal, resource. They feed upon reptiles, mollusca, insects, the smaller ground mammalia, and also upon any animal remains or offal which they can procure. They are voracious birds and appear to migrate after their food rather than in consequence of any other instinct. On their long journeys they are birds of very lofty flight ascending upwards till, notwithstanding their large size, they are barely, if at all, visible. They may be partially tamed; but there is little inducement to tame them, as they have not the interesting manners of the white storks, and their flesh is even less palatable.

**THE AMERICAN STORK** (*Ciconia magnari*) is described as differing from the white stork of the eastern continent chiefly in having the bill of an ash colour. It is white, with the wings and upper tail-coverts black; the irides white, and the feet red. It is about three feet in length. Its principal locality is said to be to the eastward of La Plata in the uninhabited part of the pampas. Some of the accounts state that it breeds in confinement, but this is contrary to the general habit of the genus.

A few more species and varieties have been mentioned, such as the small black stork of Northern Africa, and the purple stork of India; but the accounts of them are a little confused. Some notice of the great stork of India, which is an allied species, will be found under the article *ADJUTANT*; and the Jaribus will be noticed in the article *MYCTERIA*.

**CIMBEX** (Olivier: *Crabo*, Geoff.). A genus of hymenopterous insects belonging to the section *Securinifera*, and family *Tenthredinide*, and forming together with the several sub-genera which have been separated from it by Dr. Leach, (*Zaræa*, *trichiosoma*, *Abia*, *clavellaria*), a section in that family distinguished

by having the antennæ short and knobbed at the tip, and composed of only four, five, or six joints; the wings are large, with the costal and sub-costal nerves of the upper pair soldered together; the spurs of the tibiae are blunt, and the joints of the tarsi are provided beneath with spongy cushions. These insects are amongst the largest species of the saw-flies, whose curious economy in the formation of the cells for the reception of their eggs and the apparatus with which they are furnished for forming these cells will be subsequently related. They are produced from large fleshy larvæ which greatly resemble the caterpillars of lepidoptera, whence they have been termed by the French entomologists "fausses chenilles," but they are provided with a greater number of legs, the true caterpillars not having more than sixteen, whilst the larvæ of cimex have twenty-two, the eleventh segment of the body being alone destitute of these organs. It is a curious circumstance that larvæ so closely resembling each other, as those of cimex and some of the moths belonging to the family Noctuidæ, should produce insects so totally different. In their former state they both feed upon the leaves of the same tree, and their whole appearance is so similar that it would be impossible for a person unused to entomological pursuits to conceive which of the two would produce the moth, whilst in their perfect state no two insects would be found more unlike, in characters, habits, appearance and structure. The transformation of two of the largest species, *Cimex lutea* and *sylybarum*, have been observed by Lyonnet, whose excellent figures, published in his posthumous researches, represent the entire structure of the insects in great detail. The larvæ of the former, having obtained their full growth, descend into the earth in the month of July, where they form cocoons of a very firm consistence, in which they undergo their change to the pupa state, the flies making their appearance shortly afterwards.

**CIMEX** (Linnæus). A group of insects of very considerable extent, forming in the Linnæan system a single genus under this name, belonging to the order Hemiptera. In the modern system of entomology, this group has been divided into numerous distinct families, each comprising various genera and sub-genera, and the whole has been raised, under the name of *Geocoris*, or land bugs, to the rank of one of the three divisions of the heteropterous portion of the order Hemiptera, the two other divisions having for their types the genera *Nepa* and *Notonecta* of Linnæus. As a group, therefore, the *Geocoris*, or Linnæan cimex, is distinguished by the antennæ being exposed, longer than the head, composed of four or five joints and inserted between the eyes, near to their inner margins. The tarsi are three-jointed, the basal joint being often very small, the body is of an oval or oblong form, the legs are formed for running, the wings are membranaceous, not longitudinally folded, and covered, when at rest, by a pair of wing-covers, of which the basal portion is of a leather-like consistence and opaque, whilst the extremity is membranaceous and more transparent, the thorax or rather the prothoracic segment is of a large size and performs the office of a thoracic shield as in the coleoptera, whereas in the homopterous division of the order it is small; the wings and wing-covers when at rest are horizontal or at least but slightly inclined—sometimes, as in the bed-bug, they are entirely wanting. The mouth consists of an elongated and articulated proboscis, includ-

ing several fine setæ which are employed in wounding vegetable or other substances upon which these insects feed. Latreille has divided this group into various families, or rather sub-families, to which the following names have been applied:

1st. The *Pentatomidæ*, having the antennæ five-jointed, the rostrum four-jointed, the labrum or upper lip long and transversely striated.

2nd. The *Coreidæ*, having the antennæ four-jointed, the rostrum four-jointed; the second joint longer than the third, the ocelli at the same distance from each other as from the eyes.

3rd. The *Lygæidæ*, differing from the latter in having the second joint of the rostrum shorter than the third, with the ocelli placed near the eyes. The species are of small size and obscure colours, and are generally found in the ground.

4th. The *Capridæ*, being destitute of ocelli, and having the terminal joint of the antennæ very slender and the rostrum four-jointed.

5th. The *Cinclidæ* (*Membranaceæ*; Latreille), having the rostrum very short, and only two or three jointed, the labrum short and not striated.

6th. The *Reduviidæ*, having the rostrum very short, but exposed, curved, and of considerable strength, and the head is narrowed behind into a neck.

7th. The *Acanthiidæ*, having the rostrum three-jointed, but long and straight, the body of an oval flattened form, the head not narrowed into a neck, and the eyes very large and prominent. These insects are of small size, very active and frequent the borders of streams.

8th. The *Hydrometridæ*, having the body long and narrow, the four hind legs generally inserted at the sides of the body, so as to be employed in skimming on the surface of the water.

Under the word Bug we have made some general observations upon the habits and transformations of this group of insects, as well as upon the fifth of the families given above. Referring our readers thereto we shall consider the present article as one relating rather to the modern classification of the Linnæan Cimices, and shall therefore only add that M. De Laporte has lately published a valuable work upon this branch of the hemiptera, in which various other sections of inferior value are given, in the *Magazin de Zoologie* of M. Guérin.

**CINCHONA** (Linnæus). A genus of two species of Peruvian trees or shrubs, yielding the famous Jesuits' bark, so celebrated as a febrifuge. Linnæan class and order *Pentandria Monogynia*; and natural order *Rubiaceæ*. Generic character: calyx five toothed; corolla funnel shaped; limb of five spreading parts; stamens attached to the tube, sometimes included; anthers linear, two celled, bursting lengthways; style simple; stigma cleft, capsule two celled, many seeded, opening in the middle; seeds winged, with a notched margin. The bark is obtained from the trees in their native country, and exported in great quantities to all parts of the civilised world. These plants have long been introduced into British collections, but are still rare. Ripened cuttings strike root under careful management, in moist heat.

**CINCHONACEÆ**—cinchona family. A natural order of dicotyledonous plants, containing two hundred and twenty three genera, and upwards of nineteen hundred species. This order has been by many authors denominated *Rubiaceæ*, on account of the genus *Rubia* or madder, having been included under

it; as however this genus is more properly referred to a distinct order, *Stellatæ*, the name *Rubiaceæ* is no longer applicable. The order is allied to *Compositæ*, but differs in the mode of its inflorescence, in its stamens not being united, and in its ovary having two or more loculaments. To *Apocynæ* it also bears a considerable relationship, but is easily distinguished by the æstivation of its corolla, its inferior ovary and the presence of stipules. *Caprifoliaceæ* is also quoted by authors as an allied order.

The order *Cinchonaceæ* is thus characterised: calyx adherent to the ovary, simple, either undivided or with a definite number of divisions; corolla of one piece, superior, tubular, with a definite number of divisions equal to those of the calyx, and with a twisted or valvate æstivation; stamens arising from the corolla, equal in number to the lobes of the corolla, and alternate with them; anthers oval, two celled; pollen elliptical; ovary inferior, usually two celled, crowned by a disk; style single, sometimes partly divided; stigma simple, sometimes divided into a definite number of parts; fruit inferior, baccate, capsular or drupaceous, two or many celled; seeds definite or indefinite, in the former case erect and ascending, in the latter attached to a central axis; albumen copious, horny or fleshy; embryo straight or slightly curved; radicle turned towards the hilum; cotyledons foliaceous.

The plants included in this order are trees, shrubs or herbs, with simple, entire, opposite or verticillate leaves, and paniced or corymbose flowers. They grow in the hotter parts of the world, and are said to constitute a twenty-ninth part of the whole flowering plants of the tropics. They are nearly allied to each other in their properties. The barks of most of them contain an astringent bitter principle, which frequently possesses febrifuge virtues, and the roots of many of them are emetic and purgative.

This order has been divided into twelve distinct sections: 1. *Cinchonææ*, or true cinchona tribe, in which the capsule is two-celled, with a septicidal dehiscence, the cells containing many winged seeds, and the stamens being five or more. This section includes the genera *Cinchona*, *Exostemma*, *Pinckneya*, *Nauclaya*, *Uncaria*, &c. 2. *Gardeniææ*, in which the fruit is fleshy, indehiscent, bilocular, and the seeds are not winged. In this section are included the genera *Gardenia*, *Sarcocephalus*, *Genipa*, &c. 3. *Hedyotideææ*, in which the capsule is two-celled, with a loculicidal dehiscence, the cells being many seeded, and the seeds not winged. Examples of this section are seen in the genera *Hedyotis*, *Condaminæa*, *Macrocremum*, *Portlandia*, *Oldenlandia*, &c. 4. *Iseritiææ*, in which the fruit is drupaceous, and is provided with from two to six nuts as in *Iseritia*, *Metabolos*, &c. 5. *Hameliaceææ*, of which the fruit is a many celled, many seeded berry, as is seen in the genera *Hamelia*, and *Labicea*. 6. *Cordiæææ*, in which the fruit is a many celled berry, each cell containing a single seed, as in *Cordia*. 7. *Guettardaceææ*, in which the fruit is a drupe having from two to ten nuts inclosing smooth seeds. Examples are seen in the genera *Guettarda*, *Morinda*, *Vauquiera* and *Antirrhæa*. 8. *Pæderiæææ*, having a bilocular, indehiscent fruit and a fleshy albumen, as in *Pæderia*. 9. *Coffeæææ*, or coffee tribe, in which the fruit is a bilocular berry, and the albumen is horny. This section is illustrated by the genera *Coffea*, *Cephaelis*, *Siderodendron*, *Chiococca*, *Leora*, and *Psychotria*. 10. *Spermacocceææ*, in which the fruit is

somewhat dry, inclosing two or four nuts, and the stigma is bilamellar, as in *Spermacocca*, *Borreria*, and *Richardsonia*. 11. *Anthospermeææ*, in which the fruit is somewhat dry, and the stigma elongated and hairy, as in *Anthospermum*. 12. *Operculariæææ*, in which the fruit has one loculament and one seed, with a bivalvular dehiscence, as occurs in the genus *Opercularia*. To these sections many botanists add another, *Stellatæææ*, including the genera *Rubia*, *Galium*, &c., which are met with in northern latitudes. This section is, in our opinion, with some propriety reckoned a distinct order, and, as such, will be noticed by us in the course of this work.

In treating of the nine important plants which are met with in this highly interesting order we shall commence with the genus *Cinchona*, whence the name of the order is derived. This is a very extensive genus, the species of which are, however, as yet imperfectly known, notwithstanding the labours of Mutis, Zéa, Tafalla, Ruiz, and Pavon, Humboldt, and Bonpland, and the valuable monographs of Vahl and Lambert. It holds an important place in Medical Botany in consequence of furnishing Peruvian bark. There are three species mentioned in the British Pharmacopœias, *Cinchona lancifolia* which furnishes the pale bark of the shops, or the brown bark of commerce, *Cinchona cordifolia* which supplies the yellow bark, and *Cinchona oblongifolia* which is the source of the red bark. Besides these there are several other species of cinchona which produce medicinal barks, such as *Cinchona ovalifolia*, *Magnifolia excelsa*, *Ferruginea*, *Vellozii* and *Remigera*.

The cinchonas inhabit chiefly those districts of South America which are situated on the west of the Andes: some are found in Brazil, and one, *Cinchona excelsa*, grows in the East Indies. They are found at a considerable elevation, generally from six to eight thousand feet above the level of the sea, and require a mean temperature between 59° and 62° of Fahrenheit. They are handsome evergreens which attain a great height, and, when allowed to grow, acquire a considerable thickness of trunk. The stripping of the bark, an operation which is now performed on a very large scale, prevents the trunks of the trees from acquiring the same diameter as formerly. Some doubts have also been entertained as to the probability of the supply of cinchona being kept up, in consequence of no pains being bestowed on the cultivation of the trees, which frequently die after being deprived of their bark.

The bark is generally taken in the dry season during the months of September and December, and it is known to be in a proper state, when, on raising a portion of it, the air gives it a reddish colour. After removal from the tree, it is dried and separated into different sorts so as to be fit for exportation. The younger the branch is the more the bark is quilled or rolled; sometimes, however, it is quilled by the application of heat.

The cinchonas have been divided into those species having hairy, and those having smooth, corollas, the former being decidedly febrifuge, the latter not. Among the former are the species, *lancifolia*, *cordifolia*, *oblongifolia*, *ovalifolia*, *Braziliensis*, *excelsa*, &c. while the latter have been lately included under a distinct genus to which the name *Exostemma* has been given.

*Cinchona lancifolia*, pale bark, so called from the colour of its powder, is found on the declivities of hills in Peru, between 4° and 5° of north latitude,

and attains a height of thirty or forty feet. This species, from being the first introduced into Europe by Condamine, has been called, by Humboldt and Bonpland, *Cinchona Condamine*. The bark of this species generally occurs, in commerce, in the form of small tubes or quills, which are covered with a rough epidermis on which numerous lichens grow. These lichens are of importance, as indicating the peculiar quality of the bark. The bark, bearing lichens of the genera *Graphis*, *Lecanora* and *Usnea*, is esteemed good. These lichens ought to be scraped off before the bark is powdered for use. There are several varieties of pale bark, imported from Loxa and Guanaco, of which the chief are, the quilled bark of Loxa, or Cascarilla de Loxa, the grey bark of Loxa, the bark of Lima, and the Havannah bark.

*Cinchona cordifolia*, yellow bark, is a handsome tree, which grows abundantly on the mountains of Loxa and Santa Fé, in the fourth degree of north latitude, at an elevation of six or seven thousand feet above the level of the sea. The bark of this species is thicker, less quilled, and more woody and fibrous than the pale bark. It is frequently completely devoid of epidermis, and more especially when not quilled. There are two varieties of the bark in commerce, the Calisaya or royal yellow bark, and the orange yellow bark. The yellow bark is less astringent and more bitter than the pale bark.

*Cinchona oblongifolia*, red bark, grows in new Grenada, near Maraquita, in the fifth degree of north latitude. There are two varieties of this bark, the smooth red bark, or the quina roxa, or colnada of commerce, and the warty red bark of Santa Fé de Bogota, which is considered by some authors as the produce of *Cinchona magnifolia*.

*Cinchona* or Peruvian bark has been long known as a febrifuge, and seems to have been employed as such in Peru at the time of the Spanish conquest; but no accurate accounts are given of the time when it was first used. Among the many fables which have been circulated in regard to this bark, it has been stated that its efficacy in fever was accidentally discovered by a person afflicted with ague, who drank the water of a stream into which a cinchona tree had fallen, and to which it had imparted its virtues. The Jesuits in early times used to distinguish the different kinds of trees by chewing their bark, and it is said that they were attracted by the peculiar bitterness of the cinchona, and employed it in the cure of disease. On this account it long retained the name of Jesuits' bark. The name cinchona is derived from the circumstance of a cure having been effected by means of the bark, in the case of the Countess of Cinchona, lady of a Count who acted as Spanish viceroy in Lima, from 1629 to 1639.

Cinchona bark, on its first introduction into Europe, met with great opposition from medical men, who were prejudiced against it chiefly on account of its novelty. Its failure too in the cure of many diseases, for which it was at first extolled as an infallible remedy, would lead physicians to doubt its efficacy in any disease whatever. After careful observation and repeated trials, the powers of cinchona were at length fully ascertained, and its reputation as a remedy of great importance was completely established. It soon became an important article of commerce, and was admitted into the materia medica. It is now extensively used all over the world, and large quantities are annually imported into Europe from Guay-

quil, Lima, Loxa, Buenos Ayres, Carthagena, Santa Martha, and other parts of South America.

The value of Peruvian bark has frequently led to its adulteration; a considerable degree of care and attention are required in its selection. By inattention to this, and the consequent employment of spurious barks, the true article has often been brought into disrepute. Good bark is dense, heavy and dry, not musty or spoiled by moisture, and a decoction of it is red while warm, and becomes paler on cooling. Barks, which are simply internally bitter or astringent, or merely mucilaginous, whose surface is smooth or of a dark colour, whose fracture is fibrous, and internal colour white or grey, are bad, and ought to be rejected. The means of distinguishing good bark were of greater importance formerly, when the bark was constantly used in substance, than now-a-days, since the discovery of the active principles of the bark. For this important discovery we are principally indebted to the labours of French chemists, although Dr. Duncan, formerly professor of materia medica in the University of Edinburgh, was undoubtedly the first who suggested the existence of a peculiar principle in bark. By the researches of MM. Pelletier and Caventou, it has been ascertained that there exist in cinchona two alkaloids, to which the names of cinchonina and quinia have been applied, and which possess in a concentrated degree, the properties of the bark itself. These alkaline substances exist in combination with a peculiar acid called kinic acid, and their quantity varies in the different kinds of bark. According therefore as we wish to procure the one or the other, we must select a particular sort of bark for the purpose. Pale bark yields chiefly cinchonina, and the yellow furnishes quinia, with a small proportion of cinchonina, while in the red bark both these substances exist in nearly equal proportions. It will be seen that thus the barks are not only distinguished by their colour, and the other characters formerly noticed, but also by their chemical constituents. Besides these alkaloids, bark consists of kinate of lime, fatty matter, red colouring matter, tannin, yellow colouring matter, gum, starch, and lignin, or woody fibre.

By a particular chemical process we are able to separate the active principles of the bark from all the impurities which exist in it, and in this way obtain most valuable articles of materia medica. To procure cinchonina, the pale bark is powdered and boiled in water, along with a quantity of sulphuric acid or oil of vitriol. This process is repeated several times with fresh portions of acidulated water, until all the soluble matter is extracted. The decoctions thus made are evaporated and mixed with newly-slaked lime, which forms an insoluble sulphate of lime, and carries down the cinchonina as a precipitate along with it. On adding boiling alcohol to this precipitate after it is dried, the cinchonina is dissolved, while the sulphate of lime is left; and the former is afterwards procured in a crystalline state by evaporation, and may be purified by the addition of animal charcoal, and a second solution in alcohol. When thus obtained in a pure state, cinchonina is a white, crystalline salt, having a bitter taste, nearly insoluble in cold water, and requiring 2,500 times its weight of boiling water for solution. Owing to this insolubility it does not act powerfully on the animal frame, unless in combination with some acid, such as the sulphuric. The kinic acid, with which cinchonina is combined in the

bark, has no particular medicinal properties; it merely renders the alkaloid more soluble. The sulphate of cinchonia is sometimes used in medicine, but it is much inferior in tonic power to the sulphate of quinia, which is prepared from the yellow bark. In order to procure the latter salt, the yellow bark is treated in a similar manner to the pale bark, in the preparation of cinchonia, being first boiled in acidulated water, then mixed with quicklime, in order to precipitate the quinia, which is little soluble in water, but which is easily dissolved in alcohol, and afterwards combined with sulphuric acid. There is thus formed a pure white salt, which crystallises in the form of silky needles. This sulphate is now in general use, in consequence of possessing all the tonic and febrifuge properties of bark, in a concentrated state. It is capable of being administered in large doses without producing nausea, and is much more active and powerful than the bark itself. It is now manufactured on a large scale, both in this country and in France. In the year 1826, no less than 1593 hundred weight of bark was used by four chemists in Paris, and 90,000 ounces of sulphate of quinia or quinine were produced in France the same year. It is sometimes adulterated with white sugar, starch, sulphate of lime and boric acid.

Bark is employed medicinally as a stimulant tonic, astringent and antiseptic. It is administered either in the form of powder, infusion, decoction, tincture or extract. The sulphates of cinchonia and quinia are chiefly employed in the present day. Bark and its alkaline preparations are used extensively in the cure of intermittent fever, being given in large doses during the intervals or intermissions. When given in substance, bark is best administered in milk, which completely covers its flavour, provided the doses be swallowed the instant it is mixed with the milk. Bark is also used in other febrile diseases, in rheumatism, in dysentery and chronic diarrhœa, in gangrene or mortification, in various passive hæmorrhages, in scrofulous states of the system, in stomach complaints, in tic douloureux, and in various nervous and convulsive diseases. It is also used as tooth powder, and has a beneficial effect in strengthening the gums. Cinchona and its preparations ought not to be administered when there is any marked inflammatory tendency, or when there are any symptoms of an affection of the liver.

Acids in their concentrated state, white vitriol, lime water, corrosive sublimate, tartar emetic, rhubarb, and several other substances, form precipitates with cinchona, and cannot be administered in conjunction with it.

We shall next notice the genus *Coffea*, which contains thirty-five known species, some of which are cultivated in Europe. *Coffea Arabica* is the most interesting of the species, on account of furnishing the well-known article of diet called *Coffee*. It is an evergreen tree, originally a native of Arabia and Ethiopia, whence it has been transplanted into different quarters of the globe. It seems to thrive best in hilly dry soils, with a mean temperature of 70° or 75°. The tree grows to the height of fifteen or twenty feet, and has an erect trunk, two or three inches in diameter. It bears pure white, sweet-scented flowers, and roundish berries, the size of a cherry, of a dark red colour when fully ripe, and containing two seeds. These seeds are somewhat oval, convex on one side, flat and furrowed longitudinally on the other. They are

covered with a membranous endocarp, to which the name of *parchment* has been given, and which has been by many botanists improperly styled an arillus. The common beverage of coffee is made by the decoction or infusion of the roasted seeds, the part roasted being the hard or horny albumen.

Coffee has been introduced in comparatively recent times, and was totally unknown to the earlier nations, such as the Greeks and Romans. It is stated that in Caffa, a district of Ethiopia, where the coffee tree grows abundantly, the seeds were at a very early period employed as an article of food. According to Raynal, the coffee-tree was introduced from Ethiopia into Arabia, towards the end of the fifteenth century. Whether this statement be correct or not, it is well known that the tree has been long cultivated in the neighbourhood of the Arabian town of Mocha. From Arabia, coffee was early brought to Europe, and its property of producing wakefulness, and preventing sleep, seems, in the first instance, to have been the circumstance which led to its use.

Coffee-houses were established in Persia about the middle of the fifteenth century. From thence coffee was carried to Cairo, and ultimately to Constantinople, where it was publicly sold in the year 1554. In both these last mentioned cities, the use of coffee was for some time prohibited, on account of peculiar religious scruples. These however were soon overcome, and the beverage came to be universally used, particular persons being appointed by government to superintend the preparation of it. In the beginning of the seventeenth century coffee found its way to Venice, and in 1644 we find that it had reached Marseilles. The celebrated traveller Thevenot brought it to Paris in 1657, and in 1672 a coffee-house was opened in that metropolis by an Armenian named Pascal, who subsequently established one in London.

About the middle of the seventeenth century, Daniel Edwards, a Turkish merchant, brought to this country a Greek servant, named Pasqua, who understood the mode of roasting and making coffee, and who afterwards kept a coffee-house in George Yard, Lombard Street. Coffee now becoming an important article of commerce, was included in the statute-book, and a duty of fourpence was laid on every gallon of coffee made and sold. In the time of Charles II., in consequence of various political meetings taking place in coffee-houses, an order was issued that they should be shut up; this, however, was very soon rescinded. Ray says that in 1688 London rivalled Grand Cairo in the number of its coffee-houses.

From the extensive use made of coffee it became an object of importance to cultivate the tree, and accordingly we find that the Dutch, so early as 1690, transplanted the coffee tree from Arabia Felix to their settlements in Batavia. Their example was afterwards followed by the French, who introduced the plant into their possessions in the Antilles. Coffee becoming an object of interest to most nations, the tree was soon cultivated in most parts of the East and West Indies. Its produce is now known all over the world, and may be said to have become one of the necessities of life. It may be here stated that, though the coffee tree thrives well in the West Indies and the other parts of the world into which it has been transplanted, still the fruit it produces in these countries is not equal in flavour to that furnished by it in Arabia, and Mocha coffee still maintains its eminence in the market.

In the coffee plantations the trees are raised from seeds, and are afterwards transplanted into nursery lines. The plantations are situated on the sides of hills or mountains, and the trees are generally ten feet apart. The produce of a good tree is said to be one or two pounds of berries. These berries when fully ripe are gathered and put into a particular kind of mill, in order to be deprived of their outer pulp. The seeds are then soaked in water, and are subsequently well dried before being deprived of their parchment or membranous covering by means of a machine called the peeling-mill. They are afterwards subjected to the action of a winnowing-mill, which removes any loose pellicles which may be mixed with them. In this state they constitute the raw coffee beans of commerce, which require to be roasted and ground to powder before being fit for use. In this country the roasting is performed in cylinders, which are made to revolve over a charcoal fire, while in France this operation is performed generally in open pans. In Turkey a sort of coffee, called Sultan's coffee, is prepared from the fleshy mass which covers the seeds. It is said to be less heating than common coffee, and to possess gently laxative properties. The Arabs and Turks use great quantities of coffee. They prepare it very hot, and drink it without sugar at all periods of the day. The Mohammedans in India are also great coffee drinkers. They think that it allays nervous irritability, and prescribe it in cholera. The French use more coffee than the British; their coffee too is stronger, and is sometimes mixed with a large proportion of warm milk. Coffee has been a favourite beverage of many great men, Napoleon, Frederick the Great, Voltaire, and Leibnitz, were particularly fond of it. The quality of coffee is greatly dependent on the roasting; if too little done, it is heavy and has scarcely any flavour; if too much, it has a disagreeable burnt taste; whereas when the heat is properly regulated, it acquires a fine aroma, and becomes a most agreeable article of food. Coffee is frequently spoiled by being long boiled, in which case it is deprived of its fine flavour and strength, in consequence of the aromatic oil which it contains being dispelled. It is best prepared by pouring boiling water through the powdered coffee on a strainer, and various ingenious machines have been contrived for the purpose; one of the most curious of which operates on the principle of a vacuum, formed beneath the coffee to ensure the rapid passage of the boiling water through the stratum of the ground berry. By this process coffee is perfectly made, and the aroma extracted in a few seconds. Coffee ought to be used immediately after it has been roasted and ground.

The coffee trade has increased much of late, and a large amount of capital is employed in its production and transport. The consumption of coffee in Britain has increased greatly, more especially since the reduction of the duty in 1825. At present the duty charged is sixpence per pound on British Plantation, nine-pence on East India, and one shilling and three-pence on foreign coffee. In the year ending January 1831, the quantity imported into this country was 40,952,163 lbs., and the quantity exported, 28,087,994 lbs. The chief countries from which coffee is imported are, Arabia, Java, Sumatra, Brazil, and the West India islands. The quantity annually supplied by Arabia is said to be 14,000,000 pounds. The consumption of coffee over the world is thus stated:—

	Tons.
Great Britain . . . . .	10,000
Holland and Netherlands . . . . .	40,200
Germany and the countries round the Baltic . . . . .	32,000
France, Spain, Italy, Turkey in Europe, and the Levant . . . . .	28,500
America . . . . .	18,500
Total . . . . .	129,200

Coffee is recommended medicinally as a stimulant, astrigent, and antiseptic. When taken internally it diffuses a grateful warmth through the frame, soothes the system, and at the same time revives and sharpens the intellectual powers. From its property of preventing sleep, it is particularly useful to those who trim the midnight lamp. It produces all the effects of stimulating liquors, without confusing the ideas or inducing intoxication. In some peculiar constitutions it causes such a degree of irritation, accompanied with tremors and other disagreeable symptoms, that its use cannot be persevered in. When taken immediately after dinner, coffee seems to promote digestion, and it is one of the best substances for removing the disagreeable effects of opium or morphia, as well as for dissipating sick headaches arising from the previous use of stimulating liquors. In spasmodic asthma, Sir John Pringle recommended coffee without milk or sugar. Raw coffee has been used as a tonic in intermittent fevers. A decoction of it has been prescribed at Naples in chronic inflammation of the eyes, and the vapour produced during the process of roasting has also been useful in the same disease.

Coffee may be imitated by roasting rye with a few almonds. Roasted wheat and rye were lately much used by the poorer classes in Britain. In India, roasted rice has been used as a substitute for coffee; and in Europe, the roasted seeds of the common yellow water-flag have also been employed for a similar purpose.

According to MM. Robiquet and Pelletier, coffee contains a peculiar principle called caffen, a volatile concrete oil, gum, albumen, a white sweet oil, a bitter principle, and an acid resinous matter. During the process of roasting, tannin and a peculiar acid are developed.

*Coffea Mauritiana* is another species of this genus, which is found in the woods of the Isle of Bourbon. It furnishes also a kind of coffee.

*Coffea Bengalensis* is an erect shrub, found in Bengal, which flowers in the hot season, and yields fruit in the cold. It bears white flowers, which are succeeded by a small black berry. Its seeds are inferior in quality to those of the *Coffea Arabica*. Several other species, such as *Coffea racemosa* and *Zanguebaria*, produce seeds which may be used as coffee.

The next genus deserving notice is *Cephaelis*, containing upwards of thirty species, the most important of which is *Cephaelis ipecacuanha*. This is a perennial plant, found in the humid shady woods of Brazil, and other parts of South America, and is of great importance as furnishing a valuable article of materia medica known by the name of *Ipecacuan*. This medicine is procured from the root, which was first introduced into Europe as an emetic, towards the middle of the seventeenth century, by a physician named Legras. The plant, however, which yielded the root, was not known until Brotero, Professor of Botany in the University of Coimbra, in Portugal,

published an account of it in the Linnean Transactions under the name of *Calicocca Ipecacuanha*. Decandolle has since discovered that the plant belongs to the genus *Cephaelis*, and has retained the specific name *Ipecacuanha*, which is the Peruvian name of the plant, and is derived from *Ipi*, signifying root, and *Cacuanha*, the name of the district where the root is procured.

There are three kinds of ipecacuan root known in commerce—the brown, or annulated; the black, or striated; and the white. The first of these, which is exported from Rio Janeiro to Portugal, is the true medicinal *Ipecacuan* of this country, and is the root of the *Cephaelis ipecacuanha*. The root of this plant is creeping, three or four inches long, compact, irregularly twisted and knotted, and about the size of a goose-quill. It is not a continuation of the underground horizontal stem, but the offsets from that part of the stem.

The black, or striated ipecacuan, is the root of the *Psychotria emetica*, a native of Peru and New Grenada, where it is much used as an emetic. It used to be exported from Carthagen to Cadiz, but is now seldom brought to Europe, as its action is much less certain than that of the brown ipecacuan. This root is not knotted like that of the *Cephaelis*.

Another root, under the name of white ipecacuan, is sometimes introduced into commerce. This is the product of a totally different plant, *Richardsonia Braziliensis*, and is known in Brazil under the name of *Poaia Crauca*. It has a pale whitish colour, a nauseous odour, and a very acid taste. The roots of various species of *Cynanchum*, *Viola*, *Ipomidium*, and *Euphorbia*, are also imported under the general name of ipecacuan, and mixed with the root of the true species. They all possess emetic properties in a greater or less degree.

By recent analysis, it has been ascertained that the properties of ipecacuan are owing to the presence of an alkaline substance, to which the name of *emetin*, or *emetia*, has been given. In the brown ipecacuan, there are sixteen parts of this substance in the hundred; in the striated, fourteen; and in the white, only five or six. Besides emetin, the true ipecacuan contains oily or fatty matter, wax, gum, starch, gallic acid, and woody fibre. Emetin exists almost entirely in the inner ligneous, and not in the outer or cortical part of the root. The mode of procuring emetin is as follows:—Separate all soluble matter from the powdered root of ipecacuan by cold water; evaporate the solution to a certain degree in a water bath; add sub-carbonate of magnesia in excess, and afterwards evaporate to dryness; then add strong alcohol, which dissolves the emetin and resin; evaporate this tincture to the consistence of an extract; dissolve in water and again evaporate. In this way emetin is procured, mixed with some impurities. It presents the form of brown semi-transparent scales, having a bitter acid taste.

Another mode of preparation is, by first adding ether to the powder of ipecacuan, in order to dissolve the fatty matter; then boiling the resin which remains in alcohol, and afterwards treating it with magnesia. By this means emetin is thrown down, which may be dissolved in alcohol, and then evaporated, so as to obtain crystals.

In order to purify emetin, add an acid, and then an alkali, mix with animal charcoal, dissolve in alcohol, and evaporate.

When obtained in a pure state emetin is a white

pulverulent, alkaline substance, scarcely soluble in cold water, soluble in alcohol, and not in ether. In doses of a grain to three grains it produces copious vomiting, and it has been distinctly proved to be the active principle of ipecacuan.

Ipecacuan has been much employed in medicine, and has been exhibited in the form of powder, infusion and wine. Its chief use is as an emetic, for which purpose twenty or thirty grains of the powder, and from half an ounce to an ounce of the wine, are usually given to adults. In small doses ipecacuan produces sickness, and acts as a gentle laxative, while in still smaller doses it stimulates the stomach and promotes digestion.

As an emetic ipecacuan is preferable to common tartar emetic in cases where vomiting is to be produced at the same time that the stomach is to be strengthened in a certain degree, and also in cases where any bowel complaint exists.

Emetin acts more rapidly than ipecacuan in producing vomiting, and its effect is generally followed by sweating and a tendency to sleep. Ipecacuan is also used to produce sweating, more especially when combined with opium, constituting the powder commonly known by the name of Dover's powder. As an expectorant it is also frequently employed, and lozenges are made of it which are useful in coughs and catarrhs. A full dose of ipecacuan sometimes checks an accession of fever, and is useful in inflammatory eruptive diseases. In nervous diseases, bowel complaints, and cases of poisoning, the powers of this medicine are often called into action. Ipecacuan loses much by keeping, especially when exposed to light.

The genus *Psychotria* contains nearly 180 species, some of which deserve to be noticed. They are chiefly West Indian plants, bearing white flowers, and sometimes exhibiting a very beautiful foliage. *Psychotria emetica* has been already alluded to as furnishing the black or striated variety of ipecacuan.

The root of this plant differs from that of the *cephaelis*, in its cylindrical form, and in having contractions or strangulations at moderate distances with intervening striated spaces. *Psychotria herbacea* also supplies a root having emetic properties. The seeds of this species are used by the negroes in Jamaica instead of coffee. *Psychotria noxia* is accounted poisonous in Brazil. *Psychotria nitida* has received the specific name of *Mapouria*, because the mapouris, or wild cows in Guiana, feed on its leaves and branches. *Psychotria involucreata* is aromatic when dried or bruised, and an infusion of its leaves is used in asthma. One of the species, *Psychotria parasitica* is found growing as a parasite on the trees in the West Indies.

The genus *Exostemma* has been separated from cinchona in consequence of the corolla being smooth and the stamens projecting beyond it. It contains nineteen species, most of which grow in the islands of the Gulf of Mexico and on the American continent. *Exostemma caribæum* and *floribundum* yield bitter barks, which are sometimes mixed with the true cinchona. By analysis the bark of the latter species is found not to contain any trace of quinia, or cinchonina.

*Rondeletia febrifuga* yields a fever bark which is used at Sierra Leone, and barks of a similar kind are furnished by *Portlandia hexandra*, *Macrocnemum corymbosum*, *cuspidatum* and *australe*, *Guettarda coccinea* and *Coutarea hexandra*. *Portlandia grandiflora*, a

native of North America, yields a bark, called *Quina nova*, which is said to possess febrifuge properties.

*Chiococca racemosa* is a creeping shrub, like jessamine, the root of which is known in Brazil by the name of *Cainca*. This root is met with in commerce under the form of rounded pieces two or three feet long, the thickness of a writing quill, and striated so as to resemble the root of *Psychotria emetica*. According to analysis the root yields a substance analogous to emetin, which seems to be its active principle, and has been denominated *caincique* by the French. The root is used as a cure for the bite of poisonous serpents, and from its purgative properties is administered in dropsies and visceral obstructions.

*Nauclea* or *Uncaria Gambir* yields a lightish, brown, bitter, and very astringent extract, called *Gambir* or bastard catechu, which consists almost entirely of gallic acid and tannin. It is obtained at Malacca by boiling the leaves of the plant, and is used by the Malays as an astringent. It is also chewed by them along with the betel-leaves.

The bark and root of *Antirhoa verticillata* are used in the Isle of Bourbon for checking hæmorrhage. *Richardsonia rosea* and *emetica*, *Manettia cordifolia*, and *Spermacoce ferruginea* and *poaya* furnish emetic roots. The bark of the roots of *Morinda umbellata* and *citrifolia* is used in the East Indies for dyeing red and brown. The leaves of the former species are combined with aromatics in cases of diarrhœa. *Morinda royoc* is used in dyeing and in making ink. *Hedyotis umbellata* is used in India for dyeing nankeen. *Weberia tetrandria* is a thorny bush met with on the Coromandel coast bearing a reddish brown edible fruit, the size of a small bramble. A decoction of the leaves and root is used in India in dysentery and in cases of worms: the leaves are sometimes put into curries. The leaves of *Oldenlandia umbellata* are considered by the Indian doctors as expectorant, and are used in asthma. They are used in cutaneous diseases, and for the cure of poisonous bites. The root is employed at Masulipatam for dyeing cotton red. *Gardenia florida* is highly odiferous, and is made into hedges in Japan. Its seeds dye yellow. *Gardenia Rothmanna* is chiefly fragrant during the night. The fruit of *Gardenia dumetorum*, when ripe, looks like a small yellow apple. It encloses numerous strong-smelling seeds which, when bruised, have the property of intoxicating fishes. The fruit, when powdered, acts an emetic, and the bark of the root is used as an astringent.

*Genipa Americana* bears an esculent fruit which is much esteemed in Dutch Guiana. *Sarcocephalus esculentus* yields a high flavoured fruit, which has the appearance of a pine apple without a crown. Several species of *Gardenia* also yield succulent fruits which are used as food.

*Ixora pavetta* is valued by the Hindoos on account of the beauty of its flowers. Its fruit is green, and is often employed as a pickle. The genus *Siderodendron* receives its name from the hardness of its wood, which is said to resemble iron. In the species of this genus the corolla is often changed by an insect into an oblong bag, half an inch in length, fleshy and hollow within, and ending in a point at the top. *Pinckneya pubens*, genga bark, is a low tree of the United States, having a soft wood and bitter inner bark, which has been used successfully in the cure of intermittent fever.

We have thus given an extended view of the natu-

ral family of Cinchonaceæ which forms so important a part of the vegetable kingdom. In whatever way we regard this family, whether as furnishing remedies which have contributed in no small degree to alleviate the sufferings of humanity, or as supplying some of the most valuable luxuries and necessities of life, we must allow that it well merits attention, and occupies a high place among the numerous vegetable tribes which are scattered over the surface of the globe.

CINARAS (Leach). The genus *Gymnolepas* of Cuvier. This shell consists of five narrow valves, so widely placed that they do not cover the whole of the animal; to compensate for which they are enclosed in a membranous bag, a continuation of which forms the peduncle; it is of a greenish colour, with six longitudinal black stripes, three on each side; it has an anterior opening for the passage of the animal's

tentacula or arms. First class of the sub-type *Hematomopoda*, first family *Lepadicea*, of Blainville's system. The *Cinara Cranchii* is here figured.

CINDUS. See DIPPER.

CINERARIA (Linneus). A very numerous genus of herbs, undershrubs, and shrubs found in almost every part of the globe. Linnean class and order *Syngenesia superflua*; and natural order *Compositæ*. Generic character: anthodium simple, and in many parts; receptacle naked; pappus roughly pilose. The cinerarias are all pretty flowering plants, some of them singularly beautiful, and well worth cultivation. The undershrubby species are easily propagated by cuttings, and the herbaceous sorts by division of the roots.

CINNABAR. This name is given to two very different minerals, which in their external appearance nearly resemble each other. The dark red cinnabar occurs massive, disseminated, and in flakes and crystallised. Its primitive form appears to be a rhomboid, and by attrition it yields a scarlet-red streak.

Bright red cinnabar, or native vermilion, occurs in small quantities in beds and veins; in the latter, it is found in considerable quantities in Bohemia. Asia also produces this mineral, but South America may be considered as the principal source whence it is derived for commercial purposes. Cinnabar occurs in considerable quantity in the province of Antioquia, in the Valle de Santa Rosa, east from the Rio Cunca; in the mountain of Quindiu, in the pass of the central Cordillera, between Ibague and Carthago, at the extremity of the ravine of Vermellon; and in the province of Quito, between the village of Azogue and Cuenca. The cinnabar is not only found in round fragments, mixed with small grains of gold, in the alluvial soil with which the ravine de Vermellon, at the foot of the table-land of Ibague Viejo, is filled, but the miners know the vein also from which the torrent appears to have detached these fragments, and which traverses the small ravine of Santa Anna. Near the village of Azogue, to the north-west of

Cuenca, the mercury is found, as in the department of Mont Tonnerre, in a formation of quartz sandstone, with a clay base or cement. This sandstone is nearly 4592 feet in thickness, and contains bituminous wood and mineral pitch.

Compact hepatic cinnabar has a colour between dark cochineal-red and lead-grey. In its chemical constituents it differs very materially from the mineral last described; as, in addition to the mercury and sulphur found in those bodies, there is usually a considerable quantity of carbon, combined with silica, alumina, oxide of iron, copper, and water.

Cinnabar is distinguished from red silver by the red streak it affords on paper, and also in being entirely volatilised when heated; from red orpiment, by the colour of its streak, that of red orpiment being orange yellow; and from red leadspar, also by the streak, that of the lead ore being lemon-yellow.

It appears from some of the ancient naturalists, that the term Minium was derived from the name of a river of Spain; and there are several passages in Pliny, which show that the term "minium" was applied to a corresponding substance with our cinnabar. He says, that almost all the minium in use at Rome came from Spain, and that the ore was sent over from Spain sealed. He also says, that those who were employed in reducing minium to powder, wore loose bladders over the face, lest they should inhale the dust, the effects of which were very pernicious. This custom is also observed at the present day, by those who are employed for a length of time in triturating preparations of mercury. The term cinnabar was originally applied to the drug commonly called dragon's blood, which is of a dull red colour; it was afterwards transferred to the ore of mercury now under consideration. See MERCURY and SILVER.

CINNAMOMUM (R. Brown). A new genus of useful and beautiful evergreen exotic trees separated from the old genus *Laurus* of Linnaeus. It contains the true, and the base cinnamon; the camphor tree, and six others having botanical distinctions, which show their non-affinity with the laurels. They are kept in our stoves but require much attention to keep them healthy. They must be kept in a pretty high temperature; not over watered in winter, and at all times, their pots require to be well drained, lest the soil with which they are potted become soddened. They are propagated by ripened cuttings, having their leaves on, potted in sand, and covered with a striking-glass on heat.

CINNAMON-TREE is the *Cinnamomum verum* of R. Brown, formerly the *Laurus cinnamomum* of Linnaeus. This is the tree which yields the spice so called. There are eleven other species of it distributed over the islands and south east corner of the continent of Asia. Some of them are found in Japan, and most of them in the southern provinces of China. But it is on the islands of Borneo, Java, Sumatra, &c., and as far west as the island of Ceylon, that the true cinnamon tree is found, and the spice of finest quality manufactured. It is obtained from the young shoots and branches of the tree, which are about half an inch, more or less, in diameter. The united layers of inner bark, between the cuticle and wood, is the part collected; and as, when longitudinally incised from top to bottom, it shrinks spontaneously away from the wood by the heat of the sun; it is of course, easily collected and sorted for sale. The inner bark of the *C. cassia* is collected in the same way and sold as a

distinct article of commerce; but this, and the inner bark of several of the other species are too often mixed with, and sold as the true sort.

CINQUEFOIL is the *Potentilla fruticosa* of Linnaeus, a British plant, found on moist boggy places in different parts of the country. Its flowers are yellow, and rather showy, for which it is sometimes admitted as a shrubby plant in pleasure grounds. Cinquefoil belongs to the natural order Rosaceæ.

CIONUS (Clairville). A genus of coleopterous insects, belonging to the section *Tetramera*, subsection *Rhyncophora*, and family *Curculionidae*, or the Weevils. The species of which this genus is composed, although small in size, are very beautiful in their appearance, being nearly globose in form, with a moderately long curved snout, the thighs are thickened and dentated beneath, and the antennæ are ten jointed, and elbowed at the extremity of the long basal joint; the elytra are ornamented with alternate stripes, having the appearance of tessellated work. The species are found in the different states upon various plants, particularly the water betony. The type of the genus is the *Curculio scrophulariæ* of Linnaeus; it is nearly one-fourth of an inch long, the larvæ of which is covered with slime, which enables it, being unprovided with legs, to walk steadily upon the leaves by the mere lengthening and contracting the segments of the body. There are five other British species.

CIRCÆA (Linnaeus). A genus of three species of plants, two of them British. They belong to the second class and second order of Linnaean botany, and to the natural order *Onagraricæ*. The *C. lutetiana* inhabits damp shady places, and is sometimes a troublesome weed in shrubberies. It is the enchanter's nightshade of English botany.

CIRCÆACEÆ. The enchanter's nightshade family. A natural order of dicotyledonous plants, containing two genera and twelve known species. It is nearly allied to *Onagraricæ*, but differs in having a large fleshy disk, which fills up the tube of the calyx, as well as in the binary division of its flower, and in its solitary erect ovules. By some authors, however, it is considered a section of *Onagraricæ*. It bears also an affinity to the order *Haloragacæ*. Its essential characters are: calyx superior, tubular, with a two-parted limb; petals two, alternate with the lobes of the calyx; stamens two, alternate with the petals, inserted into the calyx; disk large, cup-shaped, filling up the tube of the calyx, and projecting beyond it; ovary two-celled, with an erect ovule in each cell; style simple; stigma emarginate; fruit capsular, two-celled, two-valved, and two-seeded; seeds solitary, erect; no albumen. The plants belonging to this order are herbs or shrubs, with opposite, petiolate, cordate, or ovate leaves, and racemose flowers. They are found in shady places in the northern parts of the world. They do not possess any known properties. The only genera of the order are *Circæa* and *Lopezia*.

*Circæa* is named after the enchantress Circe, from its supposed use in incantations. It contains three species, two of which are natives of Britain. *Circæa lutetiana*, common enchanter's nightshade, is frequently met with in our woods, and is also found in the woods of Canada and Nepal. *Circæa alpina* grows in wood and stony places, near the side of lakes, in the north of England and Scotland.

The genus *Lopezia* has been named in honour of the Spanish botanist, Lopez.

The various species are chiefly elegant annuals, some of which are cultivated in gardens.

**CIRCELLIUM** (Latreille.) A genus of coleopterous insects belonging to the section *Pentamera*, sub-section *Lamellicornes*, and to the family *Scarabidae*. The body is hemispheric, convex, and with the abdomen nearly semicircular, the lateral margins of the thorax are not produced into an angle in the centre; the scutellum is merely rudimental; the shield of the head is cut, at its anterior margin, into several teeth. The type of this genus is the *Ateuchus Bacchus* of Fabricius, an inhabitant of the Cape of Good Hope, an insect nearly allied to the sacred beetle of the sun, worshipped by the Egyptians, and of which a representation may be seen on the outside of the Egyptian-hall in Piccadilly.—The new species of this genus which we have figured in our plate of Beetles, is contained in the extensive collection of the Rev. F. W. Hope, president of the entomological society, whose museum is opened with the greatest liberality to the student; to whom we beg to return our thanks for the loan of this and the other new and very rare species figured in our plate; and by whom the insect of the present genus has been named *Circellium Lyceus* (one of the names of Bacchus) in allusion to its close affinity to the *Circ. Bacchus*, from which it differs in its large size, and in the different form and appearance of the teeth of the clypeus. It is an inhabitant of Sierra Leone and has not been previously described.

**CIRRHÆA** (R. Brown). A curious little plant, introduced from China, formerly called *Cymbidium* in the Botanical Cabinet of Loddiges. It is a gynandrous plant, and belongs to the natural order *Orchideæ*.

**CIRRHIBARBUS**, a genus of spinous-finned fishes, belonging to the family of *Gobioides*, and nearly related to the blennies. The characters are: the teeth in many rows, and closely set; a small tubercle over each eye, and each nostril; three large fleshy barbs on the point of the muzzle, and eight on that of the lower jaw. There is but one known species; it is a native of the Indian seas, and all over of one uniform yellow colour.

**CIRRHINES**. A genus of soft-finned fishes, with abdominal fins, belonging to the carp family; having some resemblance to the gudgeon, but with more elevated dorsal fins, and long filaments at the middle of the upper-lip. There are two known species, both Indian.

**CIRRHITES**. A genus of spinous-finned fishes, belonging to the perch family. They have crooked teeth, one dorsal fin, the gill-flap toothed, the gill-lid with a soft flap; the last rays of their pectoral fins are thick and not divided. There are several species of them, all inhabitants of the Indian seas.

**CIRRHOBANCHIATA** (Blainville). A mollusc having the organs of respiration in the form of numerous long filaments, supported by two radical lobes above the neck. Shell sub-tubular, rather conical throughout its whole length, and open at both extremities. Second class, *Paracephalophora*; 5th order, *Nucleobranchiata*.

**CIRSIIUM** (Vaillant). A very extensive genus of herbaceous plants, chiefly European. Linnean class and order, *Syngenesia Æqualis*; and natural order *Compositæ*. Generic character: scales of the anthodium spinous; receptacle dry and bristly; pappus sitting and deciduous. So numerous are the species of this genus, that botanists have divided them into

seven sections, the more easily to study and arrange them in herbariums. Before this was done, many of the species were supposed to belong to the genera *Cnicus*, *Carduus*, *Serratula*, &c. They are a tribe much more interesting to the botanist than to either the florist or the general lover of plants: their hostile thistly appearance renders them unenviable.

**CIS** (Latreille). A genus of coleopterous insects of doubtful situation, and comprising about a dozen British species of small size, having the body of an ovate-oblong form, convex above; the antennæ are short, and terminated by a three-jointed club, the joints not being soldered together as in the *Bostrichidæ*; the tarsi are composed of four joints, the last of which is longer than the rest united. The species are found in boleti, in which also the larvæ reside. It has been considered nearly allied to the death watches (*Anobium*), whilst Latreille placed it widely apart amongst his *Xylophaga*. The type of the genus is the *Anobium boleti* of Fabricius, of a chesnut colour, with the legs and antennæ lighter coloured. Its length is about one-sixth of an inch. It is found very abundantly during the summer. This genus may, be instanced as containing some of the obscure but not less available agents in supporting the great harmonies of nature. The boleti are the natural results of putrefying vegetable matter, and the species of the present genus materially assist in again turning to decay the decay-loving boletus.

**CISSAMPÉLOS** (Linnæus). A genus of hot-house and greenhouse climbers, natives of different and warmer parts of the world. They are diœious, and belong to the natural order *Menispermaceæ*. Those in our collections are easily increased by cuttings.

**CISSUS** (Linnæus). A genus of evergreen tropical climbers, long inmates of our hot-houses. Linnean class and order *Tetrandria Monogynia*; and natural order *Ampelideæ*. These plants are of no great beauty, and therefore not very generally cultivated.

**CISTELIDÆ**, a family of coleopterous insects, belonging to the section *Heteromera*, and sub-section *Stenelytra*, nearly allied to the *Helopidæ*, from which they are distinguished by having the margin of the head not produced over the base of the antennæ, which are consequently exposed; the jaws terminate in a simple point, without any internal teeth; the claws of the tarsi are denticulated beneath. The perfect insects are found upon flowers, and amongst the leaves of various trees, and it is supposed that they pass their preparatory states in the softer wood of trees; the larva of *C. ceramboides* is found in the moist and decaying parts of oak trees.

The genera introduced by Latreille into this family (which, Mr. Stephens has united with the *Helopidæ*), are *Lystrychnus*, *Cistela*, *Mycelocharus*, and *Alleca*, to which the last named author has added another British genus *Eryx*. The species are of small, or but moderate size, not exceeding one-half or three-fourths of an inch in length.

The genus *Cistela* is distinguished by the thorax being broadest behind, nearly semicircular; the jaws entire, and the body of an oval form. There are five British species, of which the *Chrysomela ceramboides* of Linnæus may be considered as the type.

**CISTINEÆ**—Cistus or Rock-rose family. A natural order of dicotyledonous or exogenous plants, containing four genera, and nearly 160 known species. It is allied to the order *Violaceæ* or *Violariæ*, and was formerly confounded with it, but it differs in

its indefinite stamens, and inverted embryo. It also bears an affinity to *Bixineæ* and *Hypericineæ*, but is distinguished from these orders by its mealy albumen, the absence of dots in its leaves and the structure of its fruit.

The essential characters of the order are: sepals five, persistent, unequal, two outer ones smaller, three inner, with a twisted æstivation; petals five, caducous, equal, wrinkled in æstivation, and twisted in a direction opposite to that of the sepals; stamens indefinite, hypogynous, distinct; anthers ovate, two-celled, inserted by their base; ovary distinct, one or many-celled; style single, filiform; stigma simple; fruit a capsule, three to five-valved, occasionally ten-valved, one-celled, with the valves bearing a single longitudinal placenta, or three to five-celled, with dissepiments proceeding from the middle of the valves, and touching each other in the centre. Seeds indefinite in number.

The plants of the order are shrubs, or herbs with viscid branches, simple, opposite or alternate leaves, and racemose flowers, which are very fugacious, and are of a white, yellow, or red colour. They are chiefly found in the south of Europe and north of Africa. A few are met with in North America, while in South America and Asia the order is scarcely known.

The rock-roses of our gardens give a good idea of this order, of which they form the chief part. Their properties are little known. Some of them yield a resinous substance possessing tonic and stimulant qualities. They are principally cultivated as ornamental plants on rock-work.

The genera of the order are *Cistus*, *Helianthemum*, *Hudsonia* and *Lecha*. The two latter are exclusively North American genera.

The genus *Cistus* gives name to the order, and is derived from a Greek word, signifying a box or capsule, on account of the peculiarity of its seed-vessel. There are twenty-eight species of *cistus*, most of which are showy plants, flowering freely. *Cistus creticus* is an elegant shrub, which grows in dry rocky places in the island of Crete, in Syria, and in several parts of the Archipelago. It was first cultivated in England in 1731. Its flowers, which are of a beautiful purple colour, open at sun-rise, follow that luminary in its course, and fall off in the course of the evening. From this species, as well as from *Cistus ladanifer*, *laurifolius*, &c., there is collected in the east a resinous matter known by the name of *ladanum* or *labdanum*. This substance is procured by drawing lightly over the shrub a kind of rake to which leathern thongs are attached in place of teeth. By this means the unctuous juice which covers the plant is collected, and is afterwards scraped off with a knife. There are two kinds of *ladanum* met with in commerce, one in masses more or less voluminous, of a blackish brown colour, and soft consistence, the other in rolled pieces of a drier and harder texture. This gum-resin, when pure, exhales an agreeable balsamic odour, and has a bitter aromatic taste. When burnt it diffuses a thick white smoke, and a pleasant perfume. As it occurs in commerce it is generally impure, being mixed with other resinous substances, and with fine ferruginous sand.

*Ladanum* is used in France as a tonic and astringent in catarrhs, dysenteries, &c., and it enters into the composition of some stimulating plasters. It is now rarely used in medicine, and is chiefly employed in fumigations, and in the formation of various perfumes and cosmetics.

*Cistus villosus* has large purple flowers, which are very ephemeral, falling off the same day they expand. A succession of fresh flowers come out daily for several months.

**CITRUS** (Linnæus). The well-known and highly-valued orange tree. Linnæan class and order *Polyadelphia Polyandria*; and natural order *Auranticeæ*. Generic character: calyx pitcher-shaped, in three or five divisions; petals five, often more; stamens compressed, variously united at the base; anthers oblong; style cylindrical; stigma hemispherical; fruit a berry of many cells, pulp composed of juicy bladders; cells containing seeds. It is scarcely necessary to observe, that the various species of this genus are among the most beautiful, most fragrant, and most useful of fruit trees. The warmer parts of the temperate zone appear to be the favourite climate of the orange; but, even between the tropics, they come to great perfection, provided the station is high enough above the level of the sea.

Whether the wild lime in the jungles of India be the original stock from which all the numerous varieties of the orange have been, in the course of time, derived, is a question admitting of no certain answer. The limes in India, and other places, are exactly alike, and bear the same relation to the orange that the crabs in the woods of England bear to the apple.

The lime, lemon, orange, and shaddock, are the most remarkable of what are called species; but between the lemon and the shaddock, there are innumerable varieties called citrons, especially in Italy: and of both the lemon and orange, there are many varieties, differing in flavour, in bulk, and in shape and colour.

This fruit tree differs from all others, in bearing two crops of fruit at the same time in different stages of their growth towards perfection;—that is to say, the young fruit of this spring 1835, do not ripen till late in the autumn of 1836, and it sometimes happens that flowers appear before the ripe fruit are gathered. On this account it is that the orange tree is impatient of frost; as there is always some fruit on the tree, which would be injured by severe cold. In all countries where the orange or lemon is cultivated, and which may be subject to the least degree of frost, precautions must be taken that the trees be defended from it. In Britain, and in other northern countries of Europe, orange trees are kept either in green-houses or conservatories, more as ornamental than as fruit trees. For the latter purpose their culture is unnecessary; seeing that the fruit are so cheaply procurable from the south of Europe. Not but that their culture to the utmost perfection is practicable in the northern latitudes, for orangeries exist in many places, where the affluent proprietors prefer plucking mature fruit from their own trees, rather than depend on the supplies from St. Michael's or the south of Spain.

As all the best varieties of the citrus tribe are truly artificial or accidental creations, they cannot be reproduced from their seed. In this respect they are exactly like our garden and orchard fruits; and, therefore, must be perpetuated by grafting or budding. The strongest stocks which can be raised from the seeds of any of the varieties are always preferred. Those from the lemon, or what is called the Madras citron, are found to be the best for the finer sorts of sweet oranges. The seeds should be sowed in the previous summer; potted off singly, as soon as possible, and forwarded so as to be ready to take the

graft in February or March. Soon as grafted, they should be placed on a dung hotbed under a glazed frame. Here, if in a proper moist temperature, the grafts will soon take, and grow away to be fine little plants by the end of summer.

Orange trees do well in tubs or boxes, in which they may be kept for many years, and until of considerable size. This is particularly convenient, where it is necessary to house the trees in winter. They require a loamy soil enriched with rotten dung; and as they do not require to be often shifted, top-dressings of sheep or cow dung are given on the top of the soil in the pots or boxes.

Where houses are built expressly for the purpose of fruiting orange trees in this country, the trees are trained to a trellis against the back wall, planted as standards along the middle, and as many kept in boxes as will fill every part of the house. The temperature of the house should be regulated according to that of the season; never lower than 45° in winter nights, and about 60° after sunset in summer. At all seasons they should have as much fresh air as possible, so as it is not too chilly; and sprinkling frequently with tepid water is of service to free from dust and discourage insects, to which orange trees are very subject. One species of coccus is a common pest; and after it has formed its scale to breed under, cannot be displaced without using the back of a knife, or sharp point of a stick. Indeed a stick pointed at one end, and a bit of sponge fixed to the other, must be frequently used to keep the trees clean.

One very important part of the management of orange trees, in order to have large and well-flavoured fruit, is the timely thinning the flowers and fruit, after the latter are fairly set. The tree is naturally extremely fruitful, and if neither flowers or fruit are mercifully thinned, the tree becomes stunted, and will neither produce healthy shoots nor sizeable fruit. The supernumerary flowers are saleable, and fetch a high price among perfumers. In the neighbourhood of Paris vast numbers of orange trees are cultivated for their flowers only; and in this country there cannot be a more agreeable ornament than an orange tree, while in flower, placed in the entrance hall of a mansion.

The shaddock, or pommelmoc, as it is called by the Portuguese, is the largest, both as to size of tree and fruit, of any of the tribe. In India, when seen loaded with fruit nearly ripe, it is certainly a magnificent object: the deep green glossy foliage, forming a dense background to the large bright yellow fruit scattered over the exterior of the branches. A full-sized fruit is not less than five inches in diameter; and, though less juicy and more acid than the orange, it is much sweeter and less acid than either the lemon or the lime. The shaddock is a dessert fruit; and so loosely are the vesicles composing the pulp attached to each other, that they are separated by the fingers, and may be eaten singly like grapes. Their qualities are considered anti-scorbutic; and homeward-bound European ships usually lay in a store of them with which to proceed on the voyage; they, however, require to be suspended singly in net bags, as they do not keep long if laid together in a locker. The lime in its wild state is, when young, a very prickly, rigid looking shrub; but becomes almost or wholly spineless when old, or when domesticated. Its juice, however, is, perhaps, superior to all others for medical and culinary purposes.

The Chinese, who may be called a nation of gardeners, possess many varieties of the citrus, and especially some excellent oranges. Their mandarin variety is a very superior fruit, and has the singular property of discharging the rind from the pulp when fully ripe. These oranges are very plentiful, and may be purchased very cheap in the streets of Canton in the season (spring), provided the seller be allowed to strip the fruit and retain the rinds, of which they make some specific use. There are also several varieties, differing in the size and flavour of fruit, manner of growth, size of leaves, &c., many of which are already in European collections.

**CIVET**.—*Viverra*. A genus of carnivorous mammalia, placed by Cuvier last in that division of digitigrade carnivora, of which the dog may be regarded as the type; and intermediate between the foxes and hyænas in the system. They have three false grinders on each side of the upper jaw and four in the under, the front ones of which are sometimes shed. There are two moderately large tuberculous grinders above, only one below, and two projecting tubercles on the interior side of their foremost carnivorous tooth below. All the rest of the grinders have their crowns more or less tuberculous. The tongue is beset with horny papillæ, harder and more pointed than in the hyænas, but not so much so as in the cats. With the exception of one of the sub-genera, there are five toes on all the feet, the claws on which are sharp and more or less retractile, but they are not very crooked. The legs are generally short in proportion to the length of the body; and the greater number use the elasticity of the arched spine to aid them in springing on their prey. Under the tail there is a scent bag, which secretes an unctuous matter, which is, in some of the species, rather abundant, has a strong musky scent, is much valued as a perfume by the Orientals, and once formed an article in the materia medica of Europe, under the name of *civet*. It is now excluded from the list of medicines; and it got a place in that list formerly, probably for no better reason than the old dogma, that "whatever seemed to have active qualities, and for which no other use could be found, must have been intended for curing some disease." In addition to this matter, of which the scent, when it has any, is generally musky, there are, at least in some of the species, two smaller openings, situated in the same part of the body, from which a dark-coloured fluid of a very disagreeable scent is discharged.

When we consider the appearance, the structure, and the habits of these animals, we find it somewhat difficult to determine to which of the other families they have the nearest resemblance. In their general form, their style of walking, and also in the possession of the anal scent bag, they bear no inconsiderable resemblance to the pole-cat or martin family; many of them have also much of the air and not a little of the manners of the hyænas; some of them also have slightly the appearance, and all have a good deal of the manners of the smaller cats; they also, in their form, the feet excepted, bear some slight resemblance to the badgers; nor is it impossible to trace points of resemblance between them and the dogs. But still they have a distinctive character of their own; and though the different sub-genera and species vary a good deal from each other, it is easy to trace a family likeness among them all. But it is much more easy to trace this likeness than to say in words in

what it consists, because it is a likeness of the whole character of the animals as made up of structure, disposition, and habit, rather than of any one of the elements which form that character.

They are all nocturnal animals; their eyes close to a vertical line in the pupil, like those of the common cat, and, as is the case with that animal, they all glisten in dull light. Some account of this glistening of the eyes of nocturnal animals may be found in the article *Cat*; and we may here add, that the reason why the eyes of the same animals do not glisten in bright daylight, is the necessary contraction of the aperture of the pupil by the action of the light upon it. In this case, the quantity of light which gets admission to the eye is very small; and therefore the portion of it which the eye reflects, is not equal to that reflected by objects illuminated in the common way; but when the animal is under the shade, if that shade is moderately obscure, the eyes glisten just as much during the day as during the night.

Animals of this genus are not entirely carnivorous, but can, when necessity urges them to it, feed upon vegetable matter, of which they prefer sweet and succulent fruits. Their proper food, however, may be regarded as being animal much more than vegetable, because the carnivorous character not only predominates in their teeth, but is more strongly marked in them than in any animals except the hyænas and cats. They are very expert in catching birds, upon which they spring much in the same manner as cats do; they also catch mice and other small animals with much dexterity, and in some parts of the world some of the species are kept in houses for this purpose. They have, however, other habits in their feeding, different from those of cats, for they are great destroyers of eggs. During the day, the greater number of them are exceedingly indolent, and sleep almost the whole of their time. Others, however, are more of diurnal animals, and follow at least some of their prey by coursing. They are all animals of tropical countries, or at least of countries bordering on the tropics; they are wholly natives of the eastern continent and the adjacent islands. There is not above one species met with in any part of Europe, and that species is confined to the warmer parts of the south, and is far from being numerous there. Africa, India, and the Oriental isles, more especially the latter, are their head quarters, and it does not appear that a single species has been met with in Australia, or in the remote isles of the Pacific. From their indolent habits, and their short legs, they cannot be expected to migrate far in quest of food, and therefore they need hardly be looked for in places which are subject to seasonal barrenness. They are not aquatic animals, however, but frequent the banks of streams, the wood-lands, or the open glades, preying generally upon the smaller reptiles and the eggs of the larger in the first of those places, on birds and small quadrupeds in the second, and on the smaller lizards in the third. They are usually divided into three sub-genera—*Civets*, *Gennets*, and *Ichneumons*, and perhaps there are some other sub-genera which may be added.

*CIVETS*. These have the scent bag large and deep, divided into two cavities, and producing abundantly the unctuous substance, which has a more musky scent in this genus than in perhaps any other. There are at least two principal species,

the civet and the zibeth, which names have, however, exactly the same meaning, though the animals differ. The civet is found chiefly in Africa, and in the south-west of Asia; the other species in the south-east; and it is probable that there are several varieties of the latter.

*Civet*. This animal is often in common language styled "the civet cat," but the name is of course inapplicable, except in some slight resemblance in the manners, in the fur on the body, and in the form of the tail.

Civet.

This species measures about two feet three or two feet four from the muzzle to the tail, and it stands from ten inches to a foot in height at the shoulder. Its muzzle is produced and pointed, but not quite so much so as the fox; the ears are short and round; the hair on the body is long and coarse, and that which ranges along the line of the back and the upper part of the tail, forms a sort of crest, which is turned back towards the neck; the ground colour is bright brownish grey, with various spots and bands of blackish brown, and the dorsal crest of the same colour; the head is whitish, with the exception of a spot round the eyes; the cheeks and chin are brown; the naked part of their nose is black; the legs and under part of the tail are brown, the hair on the former especially being much shorter than that on the body; the tail on the upper part is partially annulated.

The most remarkable peculiarity in the anatomy of the civet, is the organisation of the bag containing its peculiar scent. It opens externally by a narrow cleft, situated between the anus and the parts of generation, and is exactly similar in both sexes, which renders their apparent difference but trifling. This cleft conducts into two cavities, which might each of them contain an almond. Their internal surface is slightly covered with fine hair, and pierced with many holes, each of which conducts into an oval follicle of very slight depth, the concave surface of which is again pierced with innumerable pores. The odoriferous substance comes from these pores. It fills the follicle, and when this is compressed, it proceeds from it something in form like vermicelli, and enters the larger bag. All these follicles are enveloped by a membranous tunic, which receives many of the sanguineous vessels; and this tunic, in its turn, is covered by a muscle which comes from the pubis, and has the power of compressing all the follicles, and with them the entire bag to which they

are attached. By means of this compression, the animal gets rid of the superfluous part of its perfume. Besides this odoriferous matter, there is another secreted, which assumes the form of stiff silken threads, and is mingled with the first. The civet has besides a small hole on each side of the anus, from which a blackish and very fœtid liquid issues.

The odoriferous substance produced by the civet, and to which the animal owes its common name, forms, especially in the east, an object of considerable commerce. Its virtues are greatly vaunted, according to Baron Cuvier, among the French, though, as we have already said, its medicinal reputation is now wholly exploded.

The tail of the civet is composed of twenty-five vertebrae, which forms a difference between it and the zibeth, which has only twenty-two. We must not confound the sluggishness of this animal during the day, with incapacity of motion, at those times when its habits require it to move; for this sluggishness by day is common to all animals which prey by night; and those which pursue their prey with the greatest ardour and success, are generally the most quiet during the periods of their repose. The civet is lithe and agile, and capable either of springing like a cat, or of coursing its prey like a dog, and it indiscriminately catches birds and small quadrupeds. Failing these, it attacks fruits, and also the fleshy roots of plants. They inhabit plains and hills which are rather dry, and seldom drink. In many places of Africa they are kept and bred in a domestic state for the sake of their perfume, which still forms a considerable article of trade. The female has four mammae, but seldom produces more than two or three young. The period of gestation has not been well ascertained.

*Zibeth.* This species is much smaller in size than the civet, and smoother in its covering; but it is longer on the legs. Its length is about fifteen inches exclusive of the tail, and its height about a foot. It has no crest of prominent hairs along the ridge of the back; the ground colour of its fur is yellowish grey, marked with numerous black spots, which sometimes run so much into each other, as to form nearly continuous lines along the sides. The tail is black above throughout its whole length, and pale grey on the under side, which is also the colour of the belly. The sides of the tail are marked with cross bars of black and grey; the throat and breast are white, and so are the ears, a small spot in front of the eye, and the sides of the upper lip. The throat and breast are whitish, but marked on the sides with a very conspicuous arch of black, proceeding from the hind part of the ear, and returning to the breast, but not meeting there, so as to form a complete collar. Within the arch there is a spot in the shape of the letter V, with its point directed towards the ear.

This animal is most plentiful in the Eastern islands, where it is often kept in a domestic state, in the same manner as the civet is in Africa. When fed properly it is a very peaceful animal; though it is strongly made and very active when in a state of nature.

It is probable that two distinct varieties, if not species, of these animals, both natives of the Eastern islands, have been mixed up in the descriptions of this one. This species is called *Tauggalang* by the Malays, and the other is called *Rasse*, the latter being by far the more slender of the two, and having the line on the forehead straight, the muzzle more pointed, the head and neck much smaller, and the ears much

nearer to each other. It is a very active animal, very difficult to be tamed; will not breed in confinement, and therefore, in order to procure its perfume, which is highly prized in the east, it has to be captured and confined in a cage. It is probable that there are other varieties, or even species, besides these, but their history is obscure; and, as the colours are known to be variable in the same species, and as they all have the same structure, and nearly the same habits, the distinctions of them are of minor importance.

*Gennets.* These have the sac in which the scented matter is produced much smaller than the civets, and though they have the musky smell, there is no visible secretion, at least in any sensible quantity. The pupil of their eyes contracts more completely to a vertical line in the light than that of the civets, and their claws are more retractile, nearly as much so, in fact, as those of the cats, only they are not so much crooked, and the paw is not so well adapted for being either a striking or a clutching weapon.

*Common Gennet.* In its general appearance, the gennet bears no inconsiderable resemblance to the common pole cat, only it is rather longer and stouter, has the line of the forehead straighter, the muzzle much thinner, the ears larger and more naked, the feet stouter and the tail longer. It is covered with two sorts of hair, the longest about half an inch in length on the body, and a whole inch on the tail. The tips of the hairs are, in some places, black, others grey, and others reddish, and the tail is marked with fifteen rings, alternately white and black, with some cloudings of red.

This is a western animal, having a very considerable range in latitude, namely, from the south of France to the extremity of Africa. They sleep, or doze in indolence, during the greater part of the day, but are particularly alive during the night. They have many of the habits of cats, and are sometimes employed as substitutes. They breed in confinement, and the period of gestation is understood to be about four months.

Many other species of this sub-genus have been described, and it is probable that the *Rasse* of the Eastern isles should have been included in the number; but the history of the greater part of them is perfectly obscure, and therefore, not adapted for popular purposes.

*Ichneumons.* These have the anal bag large and simple, with the anus in the middle of it. They have the hair short on the head and the feet, the toes semipalmated, and they are generally found near the banks of rivers.

*Common Ichneumon.* Many marvellous stories have been told of the blessing which the ichneumon bestows upon Egypt, in the destruction of crocodiles and serpents on the banks of the Nile. A little more accurate information has, however, taught us to believe that the crocodile is by no means a dangerous neighbour to the human inhabitants of Egypt, neither are the serpents on the banks of the Egyptian river very remarkable for their deadly qualities; and, therefore, the ichneumon has lost much of its celebrity; and in the service which it renders to man, it must take its station below the domestic cat, though it is sometimes used as a substitute for that animal. The ichneumon is rather of a timid disposition, except against mice and small lizards; and, though it attacks the eggs of the crocodile and of other large reptiles with great courage, or, at any rate, avidity, there is no

authenticated instance of its having ventured within reach of the jaws of the crocodile. The ichneumon is not so indolent during the day as the other subgenera, and therefore it has more attraction as a domestic quadruped. It is easily tamed, remains willingly in a state of domestication, and not only obeys the call, but readily follows the footsteps of those who are kind to it.

It is rather a small animal, about fifteen inches in length and eight in height. Its colour is deep brown, so mottled with dull white, and sometimes with grey, that it is not easily described. There are five toes on each foot, the thumb is very short and apparently useless. All these toes are armed with strong and crooked claws. The sole is naked and covered with a very fine delicate skin. The eye has a long transversal pupil, but no other particular character. The nose passes the lower jaw, but is not moveable.

When the overflowing of the Nile drives the wild ichneumons from the banks, they sometimes resort to the towns and villages, to levy contributions on the poultry yards and pigeon houses (pigeons are exceedingly abundant all along the banks of the Nile), or to join in the labours of scavengery with the foxes and hyenas; but these animals not only take the lion's share of the offal, but very frequently include the ichneumon itself in that devoted portion.

The described members of this sub-genus are still more numerous than those of the former, but they are subject to the same uncertainty. Their haunts and habits are all so nearly alike, that any one of them serves to tell the tale of the others in every respect, save in external appearance and in locality. The places which they frequent, are, in all parts of the world, those in which there are periodical floodings of water; and the principal office which they appear to perform in the economy of nature, is that of destroying the eggs of aquatic reptiles, which are, in general, so very numerous, that if they were all to be hatched the young could not possibly find food.

**CLARKIA** (Pursh). A beautiful little annual, lately introduced into our flower gardens from North America. Linnæan class and order *Octandria Monogynia*; and natural order *Onagraræ*. Generic character: calyx tubular, limb four-cleft, three of them often cohering; petals inserted in the calyx, claws with one tooth on each side, limb of three lobes; stamens alternately sterile and fertile, the latter opposite the gashes of the calyx; anthers linear, two-celled; style filiform; stigma of four lobes, somewhat like petals; capsule cylindrical, furrowed, and four-celled. This plant was hailed on its first appearance, not only as a stranger, but for the elegant laciniated figure and position of its petals. It readily ripens seed, which only requires to be sowed in the open borders with other hardy annuals in the spring. The original plants had purple flowers; but we have already a variety with white or very pale purple blossoms.

**CLARY**. Is the *Salvia sclarea* of Linnæus. This is a biennial, and cultivated for seasoning soups, &c. There are two other species of clary, viz. *Horminum*, of which there are two varieties, namely—the red and purple-topped, and *Verbenaca* the vervain-clary.

**CLASSIFICATION**. The productions of nature are so numerous, and the progress which the combined and continued efforts which men of all nations and in all ages have made in the knowledge of them, is so small, compared with what we are compelled to be-

lieve still remains to be known, that the life of man, measured against all that has to be learned in order to obtain even a superficial knowledge of the works of nature, appears more disproportionate than measuring a single moment against a thousand years.

Knowledge, of whatever kind it is, in order to be true and therefore useful, must begin as we ourselves begin, that is at the point of absolute ignorance; and therefore, if we go to the details, and attempt to know the single subjects one by one, our lives would be spent before we had mastered all which is to be met with upon a single acre of ground in a state of nature. All appears in a state of confusion to our untutored observation; and therefore we, in that state, abandon the study as hopeless, and fall back upon our merely animal appetites as our only means of enjoyment.

This we find to be the state of mankind in all countries where the light of science has never came; and yet in the few matters which they do understand, we find that these men of limited information are superior rather than inferior to ourselves. The senses of the savage are always more acute than those of men who are civilised and informed; but there is no principle of progression in them—they do not advance; and we have no reason to suppose that the inhabitants of any scienceless country were one jot better informed at the time when they were first visited by European adventurers than they had been in the hundredth generation previous to that event.

Not only this, but it does not appear that there is any general tendency in them to profit by the example of their more scientific visitors, unless there has been a beginning made before the arrival of them. No doubt there are some rude people, to whom the intercourse of civilised men has given an impulse, and we cannot, perhaps, cite a more striking instance of this, than the case of the New Zealanders; but they were *begun*—had taken some steps—rude no doubt, but still in the way of improvement—before they were visited by Europeans. On the other hand, where there has been no beginning, the savage is consumed before the march of civilisation, instead of being aroused and instructed by it. The Indians of North America have faded to a remnant much faster than can be accounted for by any direct oppression with which they have met—though that has no doubt been severe enough in many instances. When we turn our attention to other parts of the world, be those parts what they may, we find that there is no exception to this; but that the longer these rude tribes have been in the neighbourhood of civilised men, the more have they fallen off in character, and declined in numbers.

There is much information involved in these truths, simple as they are; for they show that the ignorant cannot arrive at knowledge of any kind by the means and the process by which that knowledge has been originally accumulated; and also, that the way of obtaining possession of the knowledge which has been already acquired must be different from that whereby additions are made to the stock.

The record of knowledge is the *index*, as it were, while the original discovery is the labour of the book; and every one must have felt the advantage that there is in consulting a book by the help of a well-arranged index. An index to the words of any one book is most convenient for consultation, when it is arranged in alphabetical order; but an index to the productions of nature requires a different form, because each of

these singly has a story to tell, to which story, until it has been known, no name or other word can be any guide. In this case the best, and indeed the only index that can be of use is, *an index of relations*,—not an index to the individual facts or subjects, but one which shall, from the knowledge of one fact or subject, guide us to a second, from that second to a third, and so on. These relations apply equally to *what exists* and to *what happens*, and they are the means of knowledge, and not knowledge itself—the instrument, not the end. For knowledge, like every thing else, must be of the same kind with its beginning, and be stable or unstable according to the foundation on which it rests. Whether we seek to be informed, relative to the productions of nature simply as they exist, or the phenomena or changes which they display in the course of time, we must have a beginning in addition to our index of relations. Our progress, to use a homely expression, is by means of a bridge, of which facts are the piers, and relations the arches; and though we cannot pass over by means of the piers without the arches, yet the arches can have no support but the piers.

There are two sets of persons, each of which are in possession of one of these elements of knowledge without the other; and for this reason they may be both said to be ignorant. Common observers have the piers of the bridge without the arches; and men who have studied the systems in the books have the materials of the arches, but want the piers for supporting them; and thus, to them, the arches are no arches at all. Their case is much more hopeless than that of the former class; because, just as piers can exist without arches, while arches cannot exist without piers; so facts, accurately observed, are sound knowledge in the exact proportion of their accuracy and to the full extent of their number, whether the possessor of them know the relations between them or not. But still, the piers, notwithstanding all their stability, will not carry one across the river, unless they are brought so near to each other as to become stepping stones, which can be the case only in the shallows. Thus, though the matter-of-fact man is not so utterly ignorant as the mere theorist, he is still not in a condition to make advances in knowledge by means of the knowledge he already possesses; and it is the capacity of converting the knowledge which we have into the means, and the certain means, of obtaining more, which is most valuable.

*Classification*, in the natural history sense of the term, always has reference to beings or existences, and not to phenomena or appearances; though appearances are used as the means of classification; and any classification is valuable in proportion to the kind of appearance, or character as it is called, which is made the basis of it. The doing of this must depend upon the knowledge and judgment of him who makes the classification; and as the classification is the real instrument in the acquiring of knowledge, it is essential that the man who attempts to make or to alter a classification, should possess the most extensive information, and the most sound and scrutinising judgment, upon this very simple and obvious principle, that he who does not intimately know, and justly and impartially estimate all the characters (that is the known characters) of every individual which the class includes, is not prepared for giving a useful or even an honest judgment, as to what should be the common character of the class.

This applies to all classifications, and to all the parts, primary, intermediate, or subordinate, of which they are made up; and in the subordinate parts, those which come as near as possible to the specific distinctions, in which we consider things as identical in their natures, and differing only as individual existences, it is necessary to be more accurate, and to see farther than in the grand and primary divisions. In these cases, no man has a title to alter any classification, unless he is fully prepared to justify his alteration through every step and stage upward to the simplest division which can be made of natural substances, or even up to the simple fact of existence.

And it is especially necessary to impress this truth upon all who are only beginning the study of nature, or who have made but little progress in it. The beginnings of science, though mere molehills in reality, seem mountains in the eyes of the commencing student; and they seem the more so, the more earnestly and even the more honestly that he enters on the study. If we may use the expression, the eye of the mind begins the study of any thing with microscopic power, which magnifies to a very great extent; but as the quantity of knowledge accumulates, the magnifying power diminishes, and after a long life spent in scientific pursuits, individual objects sink down in their importance, and appear insignificant in comparison with the number and magnitude of the whole. Hence it is, that those men who are the best qualified, and therefore the best entitled to make or to alter classifications, always set about making such alterations with the greatest caution and reluctance. And, paradoxical though it may seem, it is nevertheless true, that all the war of systems, and all the wranglings about classifications, which have so often disturbed, and we fear we may add demented, the scientific world, especially naturalists, have really been waged by parties, not altogether dissimilar to those who are said to have fought the first pitched battles recorded by the poets of antiquity, "the frogs and the mice, the pigmies and the cranes."

With the desire of impressing this truth fully before us, we shall not venture to suggest any particular classification, or any modification of one which exists, but shall confine ourselves to a very simple outline of the meaning of the term, and of the advantages which are derivable from the right use of it.

Nature is so wide a field, that no one science can be made to embrace the whole of it with any thing like precision; and therefore when we speak of natural history in the proper sense of the words, we mean little else than a *catalogue raisonné* of a considerable number of sciences, with some slight sketch of their relations to each other. This may be considered as one primary step of classification, the beginning, as it were; and under it we are not called upon to do much more than to explain clearly what we mean by subject or being, and what by appearance or phenomenon. Some view of this, as it applies to the subjects to be known, will be found in the Introduction to this work; and all that remains would be to mention the names of the different branches of science, as applied to the knowledge of those subjects. This is, however, unnecessary, because it would be impossible, without occupying more space than we can devote to it, to make it the vehicle of much meaning. The three primary subjects are, matter which neither grows nor lives, growing matter, and living matter. The first is a very extensive subject,

and stretches in range beyond all but the very simplest and most elementary observation. It goes to the sun, to the planets, and it speculates to the stars; and in all those regions which form so mighty a volume, that the earth is but a point in its humblest page, all that we can know is distance, magnitude, mass, motion, and mutual influence of one of those bodies upon another. From this vast height, in the extreme of which we are lost in the infinitude of greatness, we descend downward to air, and water, and solid matter, whether in larger or smaller masses, and to every thing, in short, which goes to the composition of our earth, and which is not immediately under the influence of vegetable growth or animal life. Nay, our inquiry into mere matter includes the substance of which all plants and all animals are formed: and we can and do speak about the component parts of them, while they are entire, and growing, and living, just as though these component parts were separate portions of dead matter. Nor do our inquiries stop even here, for it is the province and the business of the student of dead nature, to extend his observation, and apply his reasoning, from the most distant mass to which the line in the balance can be applied, down to the very verge of the primary atom, the smallness of which makes it as inscrutable to our knowledge as it does the magnitude of the other extreme. Within these boundaries there are situated all the sciences which are physical, including chemical science among the number; and in this grand division, the name of natural history is not generally applied to any thing but to the description of those individual masses of matter which can be distinguished from each other by their peculiar characters. But still this humble portion has its use in the system, though taken singly that use is very limited.

Vegetables and animals are less extensive in their scope, because we find them only on the surface of the earth or in the waters; and their situations are generally such as that we can go all round them and examine them, and study their progressive histories in time as well as their momentary appearances. Therefore we have many more characters in the case of them, and thus it is here chiefly that classification becomes of the greatest value, and where the abuse or the captious use of it is calculated to do the most mischief. Accordingly much time has been devoted to the classifying of plants and animals; and the result of this labour, though of course, from the very nature of the case, not altogether or even nearly perfect, has made so much progress as to be highly valuable to the student, by being to him an instrument by the skilful application of which he can acquire more knowledge in a few days than he could without its assistance acquire in a life-time.

The individual classifications applying to both of these departments will be found in the notices, general and particular, of the subjects themselves; and as it would be contrary to the nature and object of a popular work to teach system-making, being the very subject which people should specially avoid attempting, we do not feel that more words are necessary.

**CLAUSILIA** (Lamarck). This characteristic name was, in the first instance, given to shells in which the entrance of the opening was closed at a certain depth by a moveable ovate testaceous lid, performing the office of an operculum, and supported by a thin elastic pedicle inserted in the columella. This lid closes upon the animal when it retreats within

its dwelling, by means of the pedicle acting as a spring. Lamarck has not been able to ascertain that all the examples he has given of this genus are so provided, but naturally concludes they should be, and has constituted the genus from the other constant and similar characters to be observed in them, the most remarkable of which is that of the termination of the last whorl being quite detached from the base of the shell. The aperture is ovate or rounded, its edge entire, and the margin reflected outwards. These shells are all of them terrestrial, fusiform, slender, and the summit rather obtuse, to which may be added, though not mentioned by Lamarck, that the opening is occasionally dentated. The structure of the animal is similar to that of the helix, but having the first pair of tentacula very short. About twelve recent species are known, the greater number of which are European, and found particularly on the borders of the Mediterranean. Several are also known from the American archipelago. Second class, *Para-cephalophora*; first order, *Pulmobranchiata*; third family, *Limacinea*.

**CLAVAGELLA** (Lamarck). This genus of shells was unknown to Lamarck in a recent state. He considered it an intermediate species between the *Aspergillum* and the *Fistulana*, differing from the former by having only one external fixed valve, the other free and internal, and from the latter, which has no perforations at the larger extremity; this shell has also an appearance of small projecting tubes at one extremity round the disk, similar to those of the *Aspergillum*. Sowerby, in his *Genera of Shells*, No. 13, has described the only recent species of this genus supposed to be known. It is classed by Lamarck between the genera *Aspergillum* and *Fistulana*.

**CLAVATULA** (Lamarck). A mollusc, united to the genus *Pleurotoma* by De Blainville, as being no other than a species of that genus.

**CLAVIGER** (Preysler). An extraordinary genus of coleopterous insects, nearly allied to the family *Pselaphidae*, having the elytra shorter than the abdomen, and truncate; the antennæ thick and six-jointed; the eyes are wanting; the maxillary palpi very minute, and apparently without articulations; and the tarsi are three-jointed, the last joint being furnished with a single claw. These curious little insects are not above one-eighth of an inch in length, and are found under stones in dry situations; they are likewise often met with in the nests of ants. M. Muller has published a good monograph upon this genus in the third volume of *Germer's Magazin der Entomologie*, as has also M. Aube, more recently, in *M. Guérin's Magazin de Zoologie*. M. Dalman has described another genus, even more remarkable than the foregoing (to which, however, it is intimately allied), under the name of *Articerus*, and which was discovered by him embedded in the substance so often mistaken for amber, namely, gum animé. The antennæ are composed of a single long cylindrical joint.

**CLAVIJA** (Ruiz and Pavon). A South American tree, which, when cultivated in a dwarfed state in our hothouses, forms a very healthy ornamental plant. Linnæan class and order, *Pentandria Monogynia*; and natural order, *Myrsinæa*. Generic character: calyx five-toothed; corolla bell-shaped, limb in five lobes; stamens shorter than the corolla, on a cup round the seed-vessel; berry having a free central placenta.

This plant was called *Theophrasta* by Linnæus and other botanists. It flowers frequently, though the little purple racemes produced from the stem are not very showy. The foliage, however, is handsome.

**CLAYTONIA** (Willdenow). A genus of tuberos rooted perennials and curious annuals from North America. They belong to the fifth class of Linnæus, and to the natural order *Portulacææ*. The annual and perennial species are sowed or planted in the open air, and thrive best on borders of moor-  
earth.

**CLEAVERS.** A very common British plant, the *Galium aparine* of botanists. It receives its name from its seeds, leaves, and slender stalks, being armed with hooked hairs, which cling or cleave to everything. It is, moreover, called goose-grass, from goslings being particularly fond of the leaves soon as they are hatched. It is a troublesome weed to the farmer, it being difficult to separate the seeds from the samples of corn. When these seeds are seen among corn, they are called burrs by the millers.

**CLEMATIS** (Linnæus.) Herbaceous and shrubby climbers, found in many different parts of the world. Linnæan class and order, *Polyandria Polygynia*; and natural order, *Ranunculacææ*. Generic character: calyx of four to six sepals; nectary, none; stamens fixed below the germen; filaments, dilated at the apex; anthers, two-celled; style persisting, downy; carpopses tailed. The clematis, or virgin's bower, or traveller's joy, is a well-known European plant. It is this plant which covers our hedges in the autumn with that grey feathery substance, by which it has also gained the name of "old man's beard." It is most abundant, and grows with great vigour, in chalky districts. The presence of chalk at a great depth under the surface is often pointed out by the existence and growth of the clematis. It is an embowering plant, and soon takes possession of the whole head of any plant it can lay hold of; the petioles of the leaves acting like tendrils, by curling round the twigs of the plant which lends support. Almost the whole tribe are attractive one way or other; and some from the easy flowing position of their branches, and elegant tassel-like flowers are much and deservedly admired. The *C. florida*, single and double; the *viticella*, and *campaniflora*, are fine plants, and merit a place in every flower garden. The hot-house species require plenty of space to flower well.

**CLEODORA** (Lamarck, *CLIO PYRAMIDATA*; Linnæus). A molluscous animal, but the posterior end of its body is covered by a firm, somewhat cartilaginous, straight, and transparent shell, like an inverted pyramid, or in the form of a spear, truncated and open at the upper part, of a distinct shape in different species, and not opened laterally, or at the posterior end, as in the genus *Hyalea*. The body of the animal is lengthened, conical, more or less depressed, divided into two parts, as in the *Hyalea*; two tentacula, two eyes, and two swimming organs at the anterior part; the posterior conical. It differs but little from the *Hyalea*, next to which it stands in the first order, *Aporobranchiata*; first family, *Thecosomata*.

**CLEOME** (Willdenow). A genus of undershrubs, perennial and annual herbs, mostly natives of America. Linnæan class, *Tetradynamia*; and natural order, *Capparideæ*. Generic character: calyx of four sepals, the fourth inferior; petals unequal, ascending, three nectariferous glands at the base; stamens many, but only a few fertile; filaments inserted

in the calyx, declining; anthers, ovate and erect; style, simple; stigma, headed; pod, stipitate or sitting, one-celled, and two-valved. These plants flower and ripen seeds readily; they are easy of management, potted in light rich soil, and may be increased by cuttings when they fail to produce seeds.

**CLERIDÆ** (Nob.; *TILLIDÆ*, Leach). A family of coleopterous insects belonging to the section *Pentamera*, and sub-section *Serricornes*, distinguished by the dilated tarsi; hatchet-shaped palpi, toothed jaws; the antennæ are more or less serrated, and often thickened at the tips; the eyes are notched internally, and the thorax is generally narrower than the elytra; the body is elongate, sub-cylindric, and of a firm consistence. These insects, in the perfect state, are often found upon flowers; many of the species, however, are only met with under the bark of rotten trees, where they have resided in the larva state. They are of a moderate size, and are generally handsome insects, being much variegated in their colours.

The larvæ, which have hitherto been observed, are carnivorous in their habits. The genera are *Clerus*, Geoffroy (*Trichodes*, Fabr.); *Cylidrus*, Tillus, Priocera, Axina, Euryypus, *Thanasimusopilus*, *Clerus*, *Necrobis*, *Corynetes*, and *Enoplium*.

The first-mentioned genus is distinguished by having the labial palpi terminated by a hatchet-shaped joint; the basal joint of the tarsi is nearly as large as the following, and the antennæ are terminated by a three-jointed club, the last joint of which is alone terminally produced into an angle. There are two British species belonging to this handsome genus, namely, the *Attelabus apiarius* of Linnæus, which is blue, the elytra red with blue bands, the extremity being also blue. The larva of this insect is found in the hive of the common bee, where it devours the larvæ of this useful insect, and thus occasions much injury to the hive. It is, however, very rare in this country. The other is the *Trichodes alvearius*, Fabr., very much resembling the preceding; but the region of the scutellum is blue, and the extremity of the elytra red. Its larvæ resides in the nests of the mason bees (*Osmia*) feeding upon the grubs of these insects.

**CLERODENDRUM** (Linnæus). Shrubs and a few climbers, mostly natives of eastern Asia. Linnæan class and order *Didynamia Angiospermia*, and natural order *Verbenacææ*. Generic character: calyx five-toothed; corolla, tube elongated, graceful, limb spreading, of five equal lobes; stamens protruding, widely parted; anthers incumbent, bursting transversely; style long, filiform; stigma acute, and cleft; drupe tetrapryrene, embraced by the calyx, one-seeded. Some of this genus are splendid flowering plants, and all are more or less ornamental. They are all easy of propagation by young cuttings, or pieces of the roots. Some of the species increase themselves by suckers.

**CLETHRA** (Linnæus). A genus of handsome hardy shrubs, natives of North America, and a few greenhouse species from Madeira. Linnæan class and order *Decandria Monogynia*, and natural order *Ericææ*. Generic character: calyx five-parted, persisting; petals five, spatulate, concave, longer than the calyx; stamens inserted in the receptacle; filaments like hairs; anthers inversely egg-shaped, opening at the apex; capsule invested with the calyx, three celled, cells full of seeds. The hardy clethras

are usually planted in light loam, mixed with two-thirds moor earth, and are very suitable shrubs for the flower garden, and are increased by seeds or layers. *C. arborea* is too tender to bear the open air of this country, and is usually treated as a greenhouse or conservatory plant. The other species, from the same island (Madeira), require similar treatment, and may all be propagated by cuttings.

**CLIDEMIA** (D. Don). A genus of tropical shrubs, separated from the genus *Melastoma*, to which they are nearly related, though not so fine flowering plants as some others of that fine natural order. The clidemias are remarkable for hairiness over their leaves and stems.

**CLIFFORTIA** (Linnæus). A genus of shrubs from the Cape of Good Hope, some of which have been long cultivated in British collections. They are *Diaceous*, and belong to the natural order *Rosaceæ*. They are cultivated more for the variety of foliage they give to the collection than for their flowers, which are not attractive. Young shoots strike root readily under the ordinary management.

**CLIO** (Lamarck). A naked molluscous animal, of which only three species are named. The characters of this animal are not sufficiently well known to

be described with certainty; it belongs, however, to the family of *Gymnosomata*. The species here figured is the *Clio borealis*.

**CLISIOCAMPA** (Curtis). A genus of lepidopterous insects, belonging to the family *Bombycidae*, distinguished by its robust thick-set body, short but powerful wings, which are rather acute, and its short curved antennæ; the palpi are of very small size, and the spiral tongue is entirely wanting. These insects are known to collectors by the name of Lackey Moths, a name which they have gained from the gaudy stripes of various colours, with which the caterpillars are ornamented. The perfect insects are of moderate size, seldom exceeding two inches in expanse. "The larvæ of *C. neustria*," observes Mr. Haworth, "are one of the greatest pests our fruit trees labour under. They are sometimes quite defoliated by these voracious caterpillars, and covered over with their noisome webs. The female moth, when she deposits her eggs in autumn, agglutinates them in the neatest manner imaginable, all in close and symmetrical contact, round a twig of about one year's growth. These, hatching a little after the foliage of the tree in spring, do not separate, but live in one society, and form themselves one common web, which they enlarge from time to time, as they find necessary to accommodate their increasing sizes, communicating at length to the almost defoliated tree, a very sickly and disagreeable appearance. The best way of destroying them, and all other tree feeding caterpillars, is to shake the branches violently either with the hand or a pole with a hook to it;

this brings them quickly to the ground, where they are easily destroyed. Poultry, if admitted, will pick them up with avidity."—*Lepidoptera Britannica*, p. 129. This insect is of a reddish-ochre colour, having a darker band across the middle of the anterior wings, margined on each side with a paler colour. It is very abundant, appearing in July and August. In certain seasons, however, from some unknown cause, it is much more rarely to be observed. It likewise attacks other trees. Thus Mr. Jenyns says of it, "The pest of our hedges, which in some seasons are entirely stripped of their leaves by the larvæ, and laid as bare as in the depth of winter." The oak, sweetbriar, sloe and hazel, are also subject to its attacks. The precise manner in which the eggs are so symmetrically deposited by the parent moth, has not been observed, but the form of the eggs themselves are admirably adapted for their spiral position, being in the form of a funnel-shaped wine-glass without a stand, so that when they are placed together in an arched form, they fit as precisely as the arch stones of a bridge, and the cement with which they are covered is so hard, that we have repeatedly slipped them off the branch without breaking the coil. We have also noticed that, although the outside of the eggs is of a dark colour, occasioned by exposure to the atmosphere, smoke, &c., yet the partition between each egg is beautifully iridescent.

It may also be mentioned, that as this cement is neither soluble in water, "nor in any other liquor," says Swammerdam, "which I have tried," they are well defended, in their exposed situations, against the wintry blasts and rains.

The curious motions of these caterpillars have attracted considerable attention amongst the observers of nature. Bonnet, who noticed a nest of caterpillars, evidently of the lackey moths, observes, "I remarked that the sound of my voice appeared to incommode them, for when I spoke they briskly agitated, with repeated jerks, the fore part of the body." He is disposed, nevertheless, to suppose that it was not by any power of hearing, but by the delicacy of their touch, that the sound of the voice was communicated to them. On the other hand, the author of *Insect Miscellanies* has suggested that this jerking motion was for the purpose of producing a rent in the skin near the head "as it was more remarkable just before their moulting than at any other time. This also, as it happens, was the very period when Bonnet made his observations, as he expressly says, 'some of them had undergone, and others were about to undergo, their first moult.'" Mr. Stephens, however, seems to refer their jerking to atmospheric causes. "In *changeable weather*, I have observed," says he "that all the individuals which happen to be resting on the *outside* of the nest, simultaneously and repeatedly elevate the anterior part of their body." For our own parts, we feel inclined to refer these motions to another cause; it will be seen that it is the larvæ on the *outside* of the nest which thus jerk themselves about; we would therefore suggest that it is for the purpose of defending themselves from the attacks of, and driving away any wandering Ichneumon fly, that they thus keep themselves in constant motion.

The other British species, *Bombyx castrensis*, is much more rare than the preceding, which it nearly resembles. It is figured by Mr. Curtis in his *British Entomology*, plate 229.

**CLISIPHONTE.** A genus of shells constituted by De Montfort, and united by De Blainville with the genus *Lenticulina*. It is only known in a fossil state, and is a microscopic shell.

**CLITHON.** A genus of shells established by De Montfort, and now united to the genus *Nerita*, of which it forms a subdivision.

**CLITORIA** (Linneus). A tropical genus of leguminous climbers, with pretty little papilionaceous flowers, which are produced abundantly if the plants are allowed heat enough. They sometimes ripen seed, from which young plants are raised; or in default of them, they may be renewed by cuttings.

**CLIVEA** (Lindley). A lately introduced hexandrious plant from the Cape of Good Hope, named in honour of the present Duchess of Northumberland. Generic character: flowers in an umbel; perianth tubular, six-parted, deciduous, parts connivent, the exterior shortest; stamens inserted in the tube, equal with each other, and with the tube; anthers versatile; style filiform; stigma trifid; berry of one seed. This plant has some resemblance to *Cyrtanthus*; but differs from that genus in having versatile anthers, and a one-seeded berry. The bottom of the stem is but very moderately bulbous; grows best in rich loam, and requires a temperate part of the stove to flower in. As it has already ripened seeds in this country it will no doubt soon be in every collection. It was called *Imatophyllum* by Dr. Hooker till it flowered, and was described by Dr. Lindley.

**CLIVINA** (Latreille). A genus of coleopterous insects, belonging to the section *Pentamera*, family *Carabidae*, and sub-family *Scaritides*. These insects are of small size, narrow form, with the thorax separated from the elytra by a narrow peduncle; the fore legs are palmated, and formed for burrowing. They are found under stones, at the roots of trees, in damp situations, beneath rejectamenta of floods, &c. There are two British species, one of which, the *Tenebrio fossor*, Linneus, is about a quarter of an inch long, and of a black pitchy colour. By the French entomologists, the genus *Dyschirius* of Panzer, &c. is united with the preceding; it is, however, distinguished by the globose form of the thorax, and some other characters. There are about a dozen British species; of the latter, some of which are amongst the smallest insects belonging to the *Carabidae*; they are found on the sea-coast, the banks of streams, &c. Their habits are very voracious, preying upon other insects.

**CLOTHO** (De Faujus). A fossil shell of an oval form, subregular, longitudinally striped, equivalve; subequilateral hinge, formed by one bifid tooth, hook-shaped, rather larger on one valve than the other; the ligament external.

**CLODBERRY** is the *Rubus chamæmorus* of Linneus. This plant is found on the mountains in the north of England and Scotland, and is a low bramble-looking undershrub. It belongs to the natural order *Rosaceæ*.

**CLOVE** or **CARNATION** is the *Dianthus Caryophyllus* of botanists, and the improved variety of the clove of florists. It ranks as the chief of stage flowers, as it combines elegance of form with variety and delicacy of colours, and to these is added the most delightful fragrance. No plant requires more of the florist's attention than the carnation; to have flowers in the greatest perfection, new plants must be raised every year. Not but that old plants will

continue to yield flowers for several years; but these being those of branches, are never so large or so fine as those on the central stem of a maiden plant. Young plants are obtained by layering the lower branches of the last year's layers; and though these be only the points of the secondary shoots, yet when separated from the parent stock, they become as independent beings, and ten times more vigorous and amplified, than if they remained on their original roots.

The cultivation of choice carnations forms a principal part of the florist's business. They have distinct names; and the superior sorts, especially if they are new, sell at high prices. New varieties are obtained from seed; but very finest age or prize flowers occur but as one in a thousand inferiors. A seedling of promising merit, may, by judicious culture, be advanced to rank with the best; and it is by accident, and such means, that our present stock of fine carnations have been in course of time obtained.

The standard choice sorts are perpetuated by annual layering. This is performed about the time, or soon after the plants are in flower. If cultivated as stage flowers, they are kept in pots, and of a pretty large size, in order that their branches may be conveniently layered. If cultivated in beds, there they are also layered; because there must be an annual supply of young plants, as well for beds as for pots.

Carnations are layered like other plants: the lower branches, which would not flower till the following year, (supposing them to be left on the parent stool) are chosen; an incision is made with a keen pen-knife, entered a little below the third or fourth joint from the top, and passed up the middle of the shoot as far as the next joint. This separated piece is called the tongue, and when the little piece below the bottom joint is cut square off, it is ready to be fixed in the soil. In layering, a little fresh compost is usually laid round the plant to receive the layers. In this, little furrows are made, and in which that part of the layer between the tongue and the root, is bent down and firmly fixed by a little hooked stick. The layer is then covered with about three quarters of an inch of the compost, and at the same time the point of the layer is gently raised upright, taking care that the tongue be kept apart from the place whence it was cut, and pressing the soil pretty closely over and around the point of the layer, to keep it in place.

New roots are soon produced at the lower end of the tongue, and towards the end of September are fit to be taken from the stools, and planted in beds or pots previously prepared for them.

Some florists are very curious in forming their carnation compost; mixing together many different substances, as loam, sand, leaf-mould, and rotten dung of various kinds. Such a compost may be very suitable; but many successful cultivators use only the freshest maiden loam, made sufficiently rich and porous by a third part of thoroughly decomposed stable or old hot-bed dung. In this, carnations, whether in pots or in beds, thrive and flower in the highest perfection, provided they receive all other necessary treatment.

The management of carnations consists, not only in placing the layers in suitable soil, but in taking care that, if potted, the pots be well drained, so that water may not stagnate within, which would materially check the growth, and spoil the beauty of the

flowers. Water must be always supplied moderately, and without excess of either moisture or dryness. The layers, when taken off the stools, are first placed in small sized pots, and usually shifted twice into larger, before they are brought to flower. The most perfect cleanliness, keeping free from weeds, and defending against snails, slugs, earwigs, and woodlice, are all indispensable through the whole course of their growth. When the stems are advancing to flower, they are often attacked by the green-fly or aphides; these must be banished by tobacco smoke, or some other means not hurtful to the plants. Props must also be fixed, to tie the stems to as they advance in height; and as several flower-pods will appear on the same stem, all but the topmost, or the two topmost, should be cut off; this is for the purpose of encouraging the principal flowers to bloom in greater beauty and amplitude.

In order to assist the flowers to expand regularly and handsomely, florists exercise certain manipulations, which are exclusively their own; these are called *hooping* and *cording*. The calyx or flower cup is liable to burst irregularly, that is, it will be rent lower down on one side than on the other; to prevent this, two expedients are practised: the first is causing the divisions of the flower-cup to open equally, by assisting the backward ones with the point of a penknife; and the second is by *hooping*, that is, by fixing a band of matting or soft string round the middle of the flower-pod, by which means the divisions of the calyx are made to burst regularly. These precautions regulate the bursting of the calyx; and in order that the corolla, or coloured petals of the flower, may be expanded laterally and symmetrically, circular cards (having a hole in the centre to embrace the calyx) are fitted on immediately behind the spreading petals of the corolla, the card acting as a support to the petals, which naturally incline to fall back. By these means the petals are exhibited in a plane; their tints and the form of the plant are seen to the best advantage, and when so dressed up by the skill of the professional florist, are certainly objects of great beauty.

These practices are only followed by flower fanciers, who exhibit their flowers at shows for prizes; and at which there is sometimes the most intense and lively competition.

**CLOVER.** The English name of several species of the *Trefolium* of botanists. The botanical name is given because the leaves are ternate, that is, three leaflets on each footstalk. Some writers have supposed that some one species of this genus is the shamrock, or emblem of the Holy Trinity, the *tria juncto in uno*, used by St. Patrick in explaining that doctrine, when preaching to the first Christian converts in the kingdom of Ireland. Others, and with more reason, have suggested that the true shamrock is the *Oxalis acetosella*, or wood-sorrel, so common everywhere in the groves of Ireland. It is true that there are several species of trefoil indigenous to Ireland as well as Britain, but none of them present the triune character so symmetrically as the leaves of the wood-sorrel; and besides, many of the trefoils being agricultural plants, they may have been originally exotics, and naturalised since the time of the patron saint of Hibernia.

Three of the trefoils are the most valuable acquisitions of the British farmer. Without them he could not make meadows of his arable fields in the short

space of two or three months; without them he could not secure large ricks of winter fodder from off fields which, in the previous summer, had borne a heavy crop of corn, and which will bear even a more valuable burden of wheat in the summer following. These clovers are the red, the white or Dutch, and the yellow flowering or black-seeded trefoil.

The red is the most luxuriant grower, and most useful as a forage plant. It is either sown alone (at the rate of about eight or ten pounds to the acre) or mixed with rye-grass and a little of each of the white and yellow sorts in the following proportions per acre, viz., of red four pounds; of white, Dutch, and yellow, two pounds each; and of rye-grass, three half-pecks. These well mixed together are sown with great regularity by experienced seedsmen, either immediately after barley or oats are sown and rolled down, or upon young wheat in the spring. In the first case one tine of the harrows covers the seeds sufficiently, and when sown upon young wheat the roller only is employed to bury the seed.

When red clover is sown alone, one summer's crops only are taken from it, because being a biennial it yields little or nothing in the third year of its standing. When sown with barley it rises therewith in the first year; much of it is mown with the barley, and makes the straw excellent winter fodder for beasts, and the stubble affords good nibbling for sheep during the cold season. In the second year it is fit to mow for hay in June, and, if not depastured after that time, a second crop may be mown and made into hay about the end of September. But if the second crop be reserved for seed, it is allowed to stand a month longer. Soon as the second crop is cut or grazed off, the clover-ley, as it is called, is immediately ploughed and sown with wheat. Red clover does not prosper if sown too frequently on the same field; the farmer therefore, in whatever course or routine of culture he pursues, always endeavours to have the crops of this clover sown at as distant intervals as possible. The intervals under ordinary management are either four or five years, that is, under the four or five course shift; but by sowing red clover alone in one course, and the white and yellow sorts with rye-grass in the next, lengthens the intervals to eight or ten years. This, as well as all other sorts of herbage intended for hay, should be mown just before they are in full flower.

The white or Dutch clover, otherwise called honey-suckle, is a perennial, and an invaluable plant in all pastures. And when a clover-ley is intended to remain down more than one year, an extra quantity of this species, say five or six pounds, must be sown on each acre. It is a creeping plant, hence the name *Trifolium repens*, but when sown with the others it rises to the height of fifteen or eighteen inches, and makes excellent sheep hay.

The yellow clover or common trefoil is also a valuable agricultural plant, and for all purposes its properties are much like those of the Dutch. It is however of quicker growth, and, if sown on a clean fallow in June, will be fit to be eaten off by sheep before wheat-seed time, a circumstance of the greatest importance to light land farmers. Besides the three sorts of clover above mentioned, there is another pretty extensively sown in laying down permanent pasture. This is the *Trifolium medium*, or cow-grass; it resembles the red clover, but is a perennial, and of a much more diminutive growth. It does not appear

to be relished by sheep, as rank tufts of it may be seen when all the surrounding herbage is closely eaten down.

A new variety of trefoil (not of the cow-grass however) has lately been introduced under the name of *T. incarnatum*, or scarlet trefoil, which bids fair to be a useful agricultural plant; and no doubt many of the species of this family or varieties of them exist, especially on the continent, which are yet unknown to farmers, but which if known might be of great importance in improving our sheep pastures.

CLOVE TREE is the *Caryophyllus aromaticus* of Linnaeus, a native tree of the Molucca Islands, cultivated for its flower-buds, a valuable spice known by the name of cloves. The tree is of a middling size, rising to the height of twenty feet or more; and as the flowers are collected by hand-picking, many labourers must be employed to get together the large quantities annually imported into Europe. Specimens of the clove tree are seen in our hothouses, but they are rare, owing to the difficulty of keeping them through the winter. They, however, may be increased by cuttings under proper treatment.

CLUYTIA (Linnaeus). A genus of evergreen shrubs from the Cape of Good Hope. Linnaean class and order *Diacia Monadelphica*, and natural order *Euphorbiaceae*. Generic character: flowers dioecious; calyx five-parted; petals five; five glands, alternating with bifid or trifid appendices seated below the germen; stamens collected in a column, diverging; anthers fixed by their back, and two-celled; styles thrice divided, and reflexed; fruit three-berried. This genus has white flowers and is rather ornamental; they are free growers and increased by cuttings.

CLYTHRA (Laicharting). A very extensive genus of coleopterous insects, belonging to the section *Tetramera*, and family *Chrysomelidae*, and distinguished from *Cryptocephalus*, to which it is nearest allied, by its longer and more cylindric body, the shortness of its antennae, which are serrated along the inner margin from the third or fourth joint to the tip. The head is often very large in the males, with the jaws stronger and more advanced in front, and the fore legs longer than in the opposite sex. There are about seventy species of this genus, described or indicated in Dejean and other works; of these not more than five are inhabitants of this country, including the typical species *Chrysomela quadripunctata*, Linnaeus, about five lines long, of a black colour, with the elytra yellowish red, each having two black spots. Its larva resides in a leather-like case, which it drags about with it. That of *Clytra longimana* lives in an oviform case, apparently of a calcareous or earthy substance, joined by a gummy cement, and covered with red hairs, the origin of which Huber, who first discovered them, could not account for.

CLYTUS (Fabricius). A genus of coleopterous insects, belonging to the section *Tetramera*, and family *Cerambycidae*, and distinguished by its globose thorax, and the shortness of its palpi, which are terminated by a large nearly triangular joint. The body is long and nearly cylindric. The antennae are not so long as the body, differing in this respect from the majority of the family. The species are of moderate size, and are for the most part elegantly marked with bands of various contrasted colours; amongst them may be mentioned the wasp-beetle, (*Leptura griesis*, Linnaeus), a very common British

species, found during the hot summer months in gardens, hedges, woods, upon umbelliferous flowers, and particularly upon the trunks of trees, within which they have passed their preparatory states. This species is generally nearly half an inch long, black, with the thorax and elytra banded with gold colour. There are five or six other British species; some, however, appear to have been imported from America in timber, and found alive in this country.

CNETHOCAMPA (Stephens). A genus of lepidopterous insects, belonging to the family *Bombycidae*, and nearly allied to *Chsiocampa*, from which it differs in having longer wings, which are "slightly reversed, obscurely diaphanous, antennae short, slightly curved, bipectinate in the males, serrated in the females; abdomen of the latter sex with a woolly mass at the apex." But it is in the interesting economy of the two remarkable species of which the genus is composed, that the more striking characters are to be found; the first of these is the *Bombyx processionea*, Linnaeus, a native of Europe, although not yet ascertained to be British. It is about an inch and half in expanse, with the wings of an ashy brown colour, those of the females having an obscure band, and of the males with three dusky streaks. It is to Reaumur that we are indebted for an account of the curious economy of the larvæ of this species, to which he gave the name of the processionary. They are found congregated in societies of six or eight hundred on the oaks, forming, when first hatched, a temporary nest on the branches; this they abandon from time to time, forming a larger camp until they have attained two thirds of their growth, when they unite their labours and construct one general nest, attached to the trunk of the tree, about eighteen inches long, composed of a greyish silk, resembling the bark on which it is attached, or rather appearing at a distance like a mass of lichens, being in shape like an irregular knob or protuberance, rising from the surface of the tree not less than four inches; between the trunk of the tree and the silken covering of the nest, an orifice is left which serves for the egress of the inhabitants, which takes place in the curious manner, whence the specific name has originated: towards sunset, when the colony go in search of food, with a regularity of the most astonishing nature, a solitary caterpillar first appears at the head of the procession, and by whose movements those of his followers are regulated; three or four then follow in a line, one by one, the head of one touching the tail of the preceding; then follow an equal series of pairs, next of threes, and so on as far as twenty or thirty; the order however is sometimes varied, by the leader being followed by two, then three, and so on. They remain amongst the leaves feeding during the night, generally returning before morning, although some may be occasionally found during the day in masses, heaped one upon another out of the nest. The larvæ shed their skin several times, and in doing so, disengage the numerous short hairs upon the surface of the body; hence Reaumur tells us, that ladies to whom he exhibited the nests upon the oak, were shortly afterwards affected, their necks, which had been bare, being covered with troublesome tumours, occasioned by the hairs lodged upon them by the wind. In like manner Reaumur suffered severely for several days, from having touched the caterpillars with his naked hands, being ignorant of the cause, and having rubbed his

eyes with his hands, he brought on a swelling of the eyelids, so that he could scarcely open them.

It is in this large nest that the caterpillars undergo their pupa state, and indeed become winged insects.

The other species, *Bombyx pityocampa*, feeds upon pines and firs in the larva state, during which it is less perfectly social than the preceding; its processional habits are nearly similar, but its powers of annoyance are much greater. In this respect this insect was known to the ancients, no less than two enactments of the Roman senate prohibiting its use under severe penalties (see *BUPRESTIDÆ*), being accounted a deleterious poison, the hairs even occasioning a very intense degree of pain, heat, fever, &c. A single specimen of this insect is contained in the British collection at the British Museum.

**COAL.** The origin of this bituminous substance will be traced under the general article, *GEOLOGY*; and we purpose confining ourselves, in the present place, to a concise view of the four principal species. These are brown coal, black coal, cannel coal, and glance coal.

Brown coal is imperfectly bituminous; in all its varieties it is fibrous, and in some of them its vegetable origin is so complete, that the remains of trunks and branches of trees are almost perfect. Brown coal burns with a weak flame and disagreeable odour. It is found in alluvial strata, and in some others of comparatively recent origin: it is subdivided into four varieties, viz. bituminised wood, earthy brown coal, compact brown coal, and moor coal.

Black, or slate coal, which is the foliated coal of some mineralogists, is very bituminous, and is used for economical purposes; it includes several varieties. It may, however, generally be said to be of a black colour, having an iridescent tarnish, and a highly resinous lustre.

Cannel coal is chiefly found at Wigan, in Lancashire, but it is more or less abundant in most collieries. It is very brittle, of a shining lustre, and burns quickly, leaving only three or four parts in the one hundred of ashes.

Glance coal is of a dark iron black, and has a bright metallic lustre. It burns without smoke, and emits no sulphureous or bituminous odour. It generally consists of comparatively pure carbon, with some silica or alumina, and a small portion of oxide of iron. There are three varieties of glance coal; the conchoidal, the columnar, and the slaty; the last of which is again subdivided into three varieties, anthracite, Kilkenny coal, and Welsh culm.

Jet or pitch coal is generally of a velvet black; it occurs massive, and sometimes in the shape of branches, with a regular woody structure. It has a brilliant resinous lustre. It is used as fuel, but the finer and harder pieces are worked into trinkets, under the name of jet.

What is called a "coal field," or district, or sometimes a "coal basin," may be regarded as a concavity, varying greatly in extent from a few to many miles, and containing numerous strata or seams of coal of various degrees of thickness, alternating with sandstone and clays, and soft slate or shale, containing impressions of vegetables, and sometimes the remains of fresh water shell-fish. The parallelism of these strata is generally well preserved. The whole arrangement is seldom any where quite horizontal, and never vertical, but always more or less inclined. Beneath each stratum of coal, there is often one of soft

clay, which rarely contains the organic remains of the overlying shale; and although the alternating strata of coal be very numerous, it is seldom that more than three or four will afford profitable occupation to the miner. The upper seam is commonly broken and impure; and few beds, less than two or three feet in thickness, are followed down to any great depth. The depth of the mines will of course vary considerably, according to the inclination of the strata, the time they have been worked, and other circumstances. Our deepest mines are in the counties of Durham and Northumberland, and the thickest beds are found in Staffordshire.

**COATI** (*nasua*). A genus of carnivorous mammalia, belonging to the division *Plantigrada*, or those which walk on the entire soles of the feet. They are found only in America, and there are but two species, the chief distinction of which is one of colour.

Their characters are: six incisive teeth in each jaw, two canines and six grinders on each side. The canines are of very peculiar form. They are not conical in their section, as is the case with those of other carnivorous animals, but flattened externally and internally, with a slight ridge on the inner surface, and trechant anteriorly and posteriorly, so as to bear some resemblance to the teeth of the sharks, only they are not serrated in their trechant edges, as the teeth of sharks are, and they have true roots inserted in *alveoli*, in the same manner as the teeth of other mammalia. They have three false grinders, the first one conical in both jaws, the two following ones tuberculous, and resembling those of the bears; the most striking external character, however, is that of the snout, on account of which they have obtained the generic name of *nasua* "nosey." This member is very much produced, extending fully an inch in advance of the incisors in the upper jaw, and being furnished with powerful muscles, resembling those that give motion to the snout of a pig. There is considerable difference, however, between the use of the elongated snout in the pig and the coati; and there is a corresponding difference in the organisation. Both snouts are adapted for digging, or routing up the ground, and perhaps, for the size of the animal, the snout of the coati is, in this respect, the more efficient instrument of the two. But the snout of the pig is the organ which guides that animal to its subterranean food, and accordingly the extremity of it is remarkably well furnished with nerves, being in fact the most sensitive part of the animal, and possessing a delicate sense of what is called touch, as well as of smell, which last does not appear to be very acute in the pig family. The snout of the coati, on the other hand, is destitute of nerves, at least in the portion which projects beyond the upper intermaxillary bone; and thus the animal has perhaps less feeling in this particular organ than in any other soft part of its body. In its substance it resembles not a little the cartilaginous pads which are found on the feet of many animals, and which, being little sentient themselves, are adapted and intended to protect the more sentient parts from external injuries. These pads are immoveable, being mere appendages to the skin, and not provided with any peculiar muscles; but the snout of the coati is not only very moveable, but the animal keeps it continually in motion, even when it is not used for its proper purpose of digging; so that one would be led to think that it does so, merely to prevent the snout from

stiffening for want of use. This is indeed simply a digging nose, and does not appear to perform any other function, at least in the lengthened part of it; and therefore it is not only a peculiarity in the animal kingdom, but it is perhaps one of the best foundations of generic distinction in the whole of zoology.

Animals of this genus have five toes on all their feet, the three intermediate ones being the longest, and the thumb or inner one the shortest of the whole. These feet are furnished with sharp and crooked claws, which are not at all adapted for digging; and indeed, though the animal dwells in burrows, it appears to excavate those burrows entirely by the action of the nose, and it is probably the only one of the mammalia which does so. The soles of the feet are furnished with tubercles, one very large one, answering to the three middle toes, very soft in its substance, but rendered adhesive by having the surface divided into smaller tubercles. The pupil of the eye contracts in the daylight to a transverse line. The ears are short and rounded; the tongue is soft and extensible like that of the bears, to which indeed these animals have a very considerable resemblance in their general character of being among the most omnivorous of the sub-order. The body is very long, as compared with the legs, which are not only short in their absolute length, but appear still shorter when the animal walks, in consequence of the whole sole being applied to the ground. The tail is of the same length as the body, of nearly equal thickness throughout, and when the animal walks it is carried recurved over the right in the same manner as in many of the monkeys. The hair over the whole body is thickly set, and of uniform length. The head is much elongated, and bears no inconsiderable resemblance to that of a fox, only the continual motion of the cartilaginous snout gives a very singular expression to the animal.

These animals are chiefly found in the forests of South America, where they assemble in small packs, and make their burrows or nesting places under the roots of old trees. This habit is a necessary consequence of the peculiar form of their digging instrument; for as the snout necessarily digs by an upward motion, it is obvious that it cannot dig so as to leave a firm roof, as is the case with those animals which dig downward or laterally with the paws; indeed, it is quite evident that an upward digging animal could not possibly get under a roof of earth at all, unless it were to burrow in the face of a perpendicular bank, and these animals are found in the dry forests, rather than by the margins of the waters. It is said that they often undermine the trees to such an extent, that when even a moderate wind comes, they are overturned in great numbers; and thus the coats serve, to a very considerable extent, as foresters or woodmen, in cutting down, or which comes to the same thing, uprooting those trees which have begun to encumber the soil. They are by no means inexpert, as they climb, and pursue birds, and also rob nests in the trees. Contrary to the general habit of climbing mammalia, they descend the trunks of trees head-foremost, and they do this in consequence of a peculiar mode which they have in reversing the hind feet externally, and thus suspending their weight by their crooked claws. It is said that in a state of nature, there are many more males produced than females, and that the bachelor coats live solitary in the woods.

As their motion on the ground is very slow, and as they are incapable of digging so as to bury themselves, they are easily taken, and they do not refuse to live in a state of confinement, in which indeed they are very tame, and fond of being caressed, though they do not follow their masters, or show much attachment in return. While feeding, they are suspicious animals. They use their fore-paws as hands in feeding, and also in dividing their food, so as to fit it for being received into the mouth. They are very restless and inquisitive in their manners, continually moving about.

As already mentioned, there are only two species, both natives of South America; and it is doubtful whether even these are any thing else but varieties differently coloured, but the differences of colour is very considerable. These two species are the red and the brown.

*The red Coati* has all the parts of the body of a bright red, with the exception of the muzzle, the ears, the soles of the fore feet, and some spots or bands on the tail, but the ridge of the back is darker than the rest, and has a blackish tinge. The muzzle is greyish black on the upper part, and grey on the sides; and there is a white spot surrounding each eye. The covering is everywhere of very thick and rough hair, which consists of two sorts. The colours appear to be subject to considerable variations. The smell of the animal is strong and offensive.

*The brown Coati* is still more variable in colour than the red; but its most constant character is described as being two white lines, which extend along the sides on the back of the muzzle, and meet the circles which surround the eyes. The most decided character, however, is described as being the different number of mammae in the females, the red having five pairs, and the brown only three; but it does not appear from all the information which we possess, that the number of young in the red is equal to that of the mammae, as is the case with most of the animals of South America. We are, however, in a great measure ignorant of the manners of the coats.

**COBÆA** (Cavanille). A Mexican ornamental climbing perennial, common in greenhouse collections. Linnæan class and order *Pentandria Monogynia*, and natural order *Cobæaceæ*. Generic character: calyx bell-shaped, five-cleft, peltate at the base and persisting; corolla bell-shaped, five-lobed, lobes three-cleft; stamens declining, filaments twisted; stigma three or five-cleft; capsule inversely egg-shaped, from three to five-celled, all the valves opening, seed imbricated and margined. This plant having large purple flowers, fine foliage, and a free grower, is a great favourite, especially for hiding the columns in a conservatory, or covering the back wall of a greenhouse. In the summer months it grows well in the open air, and quickly forms a bower over any kind of trellis or veranda, which it may be desirable to cover with verdure and showy flowers. As it ripens seeds, new plants are easily raised, or it may be increased by cuttings in moist heat. The *C. scandens* was formerly included in *Bignoniaceæ*, but now forms an order by itself.

**COBALT**. This metal is rarely found pure in a native state. The cobalt from Tunaberg in Sweden is combined with sulphur; in other cases it is mineralised by arsenic; and both of them much resemble iron pyrites in form and colour. At one place in

Hungary, cobalt occurs combined with sulphuric acid, forming stalactites of a pale rose colour. The hexahedral cobalt pyrites occurs principally in Norway and Sweden. This may be considered as one of the most common species of cobalt, and is that from which the cobalt of commerce is principally obtained. It is peculiarly distinguished by its silver-white colour, great hardness, and weight. Octahedral cobalt pyrites occurs in Cornwall, and in several parts of the continent of Europe.

This mineral derives its name from one of the superstitions peculiar to the German miners, where it was first found. The great mines in that country are still supposed to be haunted by evil spirits, named "Kobolden;" and those minerals which had the appearance of rich ores, but which in reality afforded nothing valuable, were considered as the production of these spirits, and were hence named Kobold. A large proportion of the cobaltic ores, now so well known to the scientific mineralogist, were thus, through the ignorance of the miners, thrown away as useless, under the name of kobold or cobalt.

COBITIS (Loche). A genus of soft-finned fishes, with abdominal fins, belonging to the carp family, the characters of which are: the head small, the body elongated, the skin covered with small scales, and having a copious mucous secretion; the ventral fins placed far backwards, and over them one small dorsal; the mouth, at the end of the muzzle, small in the opening, and toothless, but furnished with fibres, and having the lips so formed as to serve for a sucker; the gill-openings very small, and furnished with three rays only. The lower bone of the pharynx strongly toothed; they have no cæca, and their air bladder is very small, adhering to the third and fourth vertebrae of the spine. There are several species, three or four of which are natives of the fresh waters of the more temperate parts of Europe. They are very small fishes, and of minor importance, though the flesh of some of them is considered a delicacy. Only two of this genus are mentioned by ordinary writers on British fishes.

*The Loche (C. barbatula)*, is found in some of the clear running streams of the southern parts of Britain. It is a small fish, only about four or five inches long, and of a yellowish colour, clouded and spotted with blackish-brown, and the under part white. The mouth is very small, with a beard or filament at each corner, and four in front of the snout. It spawns early in the season, about the month of April. Its flesh, though small in quantity, is of a good flavour. This species lives only in running streams; but still Frederick I. of Sweden, contrived to have it transported to that kingdom, to serve as a *bonne bouche* at his royal table.

*The Groundling (C. tenia)* is rather smaller than the common loche, and is distinguished from it by a forked spine under each eye, which is moveable. The ground colour of this species is orange, and the spots black. It is not known in so many parts of England as the other, probably because it is in no estimation for the table. It inhabits running waters, and is found lurking among stones.

*The pond Loche (C. fossilis)*. This is a much larger species, attaining sometimes the length of about a foot. This species inhabits still waters, such as ponds and ditches, in the sludge and mud at the bottom of which it buries itself to a considerable depth, and will continue to live there for a long time, when the

water is frozen, or when it is dried up. This species has two cirri or barbules at the mouth. It is long and slender, and beautifully striped across with brown and yellow. Its flesh is not only in small quantity, but of indifferent quality, soft and of a disagreeable smell; but the fish is, notwithstanding, often kept in glasses as a matter of curiosity.

The beauty of its colours, and the liveliness of its motions, form part of its attractions; but not the only, or, indeed, the principal ones. It is exceedingly sensitive to changes of the atmosphere, and therefore it serves as a sort of barometer, or rather "weather wiser." We might refer this property of it, from the habit which it has of burying itself in the mud, as the same habit is attended by similar sensitiveness in leeches and several other creatures. It seems indeed to be a pretty general law of nature, that animals which live in the mud at the bottom of waters are much more delicate to atmospheric impressions than those which inhabit nearer at top. Of this we have a remarkable instance in the common eels, which, even in the warmest parts of England, descend the rivers, and bury themselves in the mud and sludge of the estuaries, during the winter months, while many of those fishes which inhabit much nearer the surface, actually ascend the rivers at the same season. There is no doubt something physiological in this habit of eels, and that they seek the high temperature of the top of the brackish water, in order to bring forward their spawn; but still, as this act is purely instinctive, and not the result of any speculation or design in the eels themselves, it must be dependent on natural causes, and the only cause to which we can assign it, is the influence of atmospheric change upon their bodies.

The pond loche appears to be more susceptible than even the eel. When the weather is boisterous they come to the surface, and seem to partake of the turmoil of the atmosphere, by driving about with great rapidity; and from the lightness of their make, and the liveliness of their motions, their appearance is very interesting. On the other hand when the weather is cold and sullen, they sink down to the bottom of the glass, and remain in a state of complete repose. It has been said, and alleged and proved by positive experiment, that these fishes are in the constant habit of swallowing air, which they discharge from the vent, converted into carbonic acid gas. This allegation is so contrary to the general habits of fishes, who do not even breathe free air, and so different from the habits of all animals in the fact of discharging carbonic acid from the bowels, that it would require to be established by very nice and very frequently repeated experiments.

*Three-bearded Loche (C. tricirrhata)*. This species has been found in the running brooks about Rouen, about the time of the vernal equinox, with the milt and roe in a state of great forwardness. It is reddish-brown on the upper part, with small spots of a darker colour; and the under part, together with all the fins except the dorsal and the caudal, are clear straw-colour; these two fins are blackish.

Several species of loche are mentioned as inhabiting the brooks and tanks of India; and there is little doubt that there are many species yet to be discovered in various parts of the world. It appears, from the remains of fish imbedded in the earth in a fossil state, that this genus was very abundant in former times; for even the species with which we are at

present acquainted, as living inhabitants of the fresh waters, are found imbedded in the earth, though only, we believe, in fresh water formations. Indeed from the habit which these fishes have of burying themselves in the mud, we might easily conclude that small and feeble as they are, they are much more likely to be preserved in the soil, than more powerful fishes, which have no such habit; for we have only to suppose that the return of the water to their temporarily dry haunts is accompanied, as it often must be, with a mass of stones and gravel of considerable thickness, in order to see how they must frequently be buried in the earth to such a depth, as to be equally beyond the power of escape, and the chance of decomposition. By attending to the habits of those animals, which are found both in a living and a fossil state, we are often enabled to make the past and the present history of the animal kingdom throw light upon each other.

**COBURGHIA** (Sweet). A hexandrious bulbous plant introduced from South America, which was first called *Pancratium incarnatum* by Kunth, but described and figured in Sweet's Flower Garden, and re-named by the author in honour of Prince Coburg, now king of Belgium.

**COCCIDÆ** (Leach; *Gallinsecta*, Latreille; genus *Coccus*, Linnaeus). A family placed by Latreille in the order *Hemiptera*, and sub-order *Homoptera*, but considered by De Geer and some of the most recent French entomologists as forming the type of a distinct and very anomalous order. The species of this family, which are generally called scale insects, are of small size, having, in the winged individuals, short legs, with only two joints to the tarsi, and a single hook at the extremity of each. The male is destitute of a mouth, but is furnished with two large wings and a pair of small appendages behind the wings, resembling the poisers of the diptera; the abdomen also in this sex is terminated by two or more slender filaments. The antennæ are moderately long and filiform, the number of joints not exceeding eleven. The females on the contrary, in their perfect state, are amongst the least perfectly organised of insects, appearing only as an inert scale-like mass, destitute of legs or antennæ, and affixed to the bark of various trees and plants, which consequently appears, from the number of individuals collected together, to be covered by a vast number of galls of an oval or rounded form; these are, however, female cocci affixed to the plant. In their early stages, however, these insects are smaller and more active, having much the appearance of tiny red tortoises, and feeding like their parents upon the stems or leaves, which they pierce by means of a long and sharp rostrum, which goes to the very centre of the shoot, causing the sap to flow in abundance, or bleeding the plants as it is termed, and by which means great injury is done, especially to the vines, which are liable to be much infested with them; and which are thereby sometimes rendered barren. In this state they continue growing in size for some time, but the period soon arrives when the sexes undergo a very singular difference in their transformations. All the insects now affix themselves to the surface of the plants or stems, the little activity which they had previously possessed entirely ceasing. The males discontinue to increase in size, and if one of them be opened carefully, a small and elegant chrysalis will be found within the old skin of the larva; the females, how-

ever, continue to increase in size until they are many times larger than the other sex, the margins of the body being glued down to the plant, the body being by degrees distended by a very great number of eggs until nothing more than the upper and under skins of the insect remains. Soon afterwards the male fly, of a very elegant form makes his appearance, and being unprovided with any means of taking food is adapted only for continuing the species. After impregnation the female commences the deposition of her bag of eggs, but the mode in which this is performed is quite unlike what takes place in other insects; immediately beneath her body is a layer of white gummy matter, in the midst of which the eggs are deposited, and which prevents them from sticking to the rind of the bark, so that they are pushed by degrees beneath the body, which at last becomes nothing more than a thin covering composed of the upper and under pellicles, under which are now to be found the eggs which had before been between them. The female then dies, and the young ones when hatched make their way from beneath this scaly covering, again to perform a like succession of ravages. These insects are often so injurious that various plans have been resorted to for destroying them, such as scraping the bark, washing it with soap and water, or a decoction of bitter aloes, &c.

Some of the species of this family are highly prized for the fine red dye which they afford, amongst these the most valuable is the cochineal insect (*Coccus cacti* of Linnaeus), an inhabitant of Mexico, where it is cultivated upon a species of opuntia. In our botanical article *CACTÆ* is given an account of its habits, &c. In the last part of the Annals of the Entomological Society of Paris, we find it stated, that the French colonists of Algiers have undertaken the cultivation of the cochineal with great success. There have been three generations of the insect in the course of a year and a half, and in a very short period 1000 square feet of cactus will be inhabited by this precious insect, so that it may be fairly said to be acclimated in that colony as we find Algiers now termed. Another species, *Coccus adonidum*, is very abundant in our hot-houses, where it does much injury to the vines; it deposits its eggs in an envelope of white cottony matter. Dr. Kidd has published an interesting account of it in the Entomological Magazine, vol. ii. We have already, in our article *CHERMES*, given a notice of the distribution of this genus, and shall therefore only here mention, in addition, that various other genera have recently been proposed by M. Gene, in the Fauna del Regno di Napoli; and that in the curious allied British genus *Dortheisia*, the female does not lose the power of locomotion, the male having the abdomen terminated with numerous long and very delicate white hairs.

**COCCINELLIDÆ** (Latreille). A family of coleopterous insects belonging to the section *Trimera*, and including the insects familiarly called lady-birds, lady-cows, &c. The body is nearly hemispherical, the thorax short, transverse, somewhat lunate, the antennæ are very short, and terminated by a compressed inarticulate club, the terminal joint of the palpi is large and hatchet-shaped, and the tarsi are composed of only three joints, of which the second is deeply cleft. This family corresponds with the Linnaean genus *Coccinella*, and comprises an extensive series of small but pretty insects, having the body

ornamented with spots and marks of various colours, amongst which black, yellow, and red are most conspicuous. They appear early in the spring, and are amongst the earliest of our youthful recollections; they creep but slowly, although they fly well, and are found upon various plants, especially those infested with aphides; hence the injury done by the latter insects has by ignorant persons been attributed to the coccinella, whereas so far is this from being the case, that the last-mentioned insects feed, on the contrary, upon the aphides both in the larva and perfect state, and never touch the vegetables infested. The eggs are laid in patches on various kinds of leaves in the midst of the aphides, and are of a bright yellow colour. The larvæ when hatched are accordingly in the midst of their food. They are very active, provided with six legs. The body is depressed and elongated, gradually narrowed behind to a point, and furnished at the extremity with a fleshy tubercle which is employed as a seventh leg, and by which on assuming the pupa state they attach themselves, with the aid of a glutinous secretion, to the under side of leaves, where their skin by degrees wrinkles up, the body of the pupa being much shorter than that of the larva. The imago is produced in about twelve or fifteen days. There are several broods in the course of a year; the service which these insects render to the agriculturist must be very great when the vast myriads of coccinellæ, which are occasionally noticed, are taken into consideration. In the "Introduction to Entomology," we find various statements relative to their appearing, in certain seasons, in immense profusion, especially upon the sea coast, to the no small alarm of the superstitious, by whom they were regarded as forerunners of some direful evil, and who were, of course, ignorant that these little visitors were emigrants from some neighbouring hop-ground, where each had slain his thousands and tens of thousands of the aphides, which, under the name of the fly, so often blasts the hopes of the hop-grower. In France they are regarded as sacred to the Virgin, and are accordingly called *Bêtes de la Vierge*; *Vaches à Dieu*, &c. Even the hop-growers are beginning to be sensible of their services, and hire boys to prevent birds from destroying them. It may also be mentioned that it is an easy thing to clear a favourite plant from the destructive aphides by placing upon it several larvæ of the lady-cows, or of some of the aphidivorous flies, which may constantly be found in the midst of the plant-lice upon other neighbouring plants. When these insects are touched they immediately fold up their legs, and emit from the joints a yellow mucilaginous fluid of a very disagreeable odour, and which in the common seven-spotted lady-bird, *C. septem-punctata*, has been considered as a remedy for the toothach. The variations in colour exhibited by some of the individuals of the same species is very striking, and has caused great confusion in the systematic description of these insects, varieties having been regarded as species, and *vice versa*; moreover, individuals of different colours are found coupled together, but the result of this kind of union has not been observed.

The genera belonging to this family are *Chilocorus*, *Coccinella*, *Sphaerostoma*, *Scymnus*, *Rhyzobius*, and *Cacicula*, all of which are British. Latreille likewise adds, in the Règne Animal, two other genera, *Lithophilus*, which is nearly allied to *Triplax*, and *Clypeaster*, which is more naturally placed by Mr. Stephens with *Phalacrus*, &c.

The genus *coccinella* is distinguished by having the elytra smooth, without rows of punctures, and destitute of pubescence, and the thorax is angulated behind. There are about thirty species of this genus, varying in length from one-third to one-eighth of an inch, nearly all of which are subject to a very great variation in colouring. The type of the genus, and one of the largest and commonest species, is the *C. septem-punctata* of Linneus, mentioned above, and is of a red colour, the elytra having seven circular black spots.

**COCOLOBA** (Linneus). A genus of fruit, timber, and ornamental West-India trees, belonging to the eighth class and third order of the sexual system, and to the natural order *Polygonææ*. Generic character: calyx five-parted, persisting, and at last becoming thick; corolla none; filaments awl-shaped; anthers twined; style spreading, nut one seeded; berry included in the persisting calyx. Most of these plants have very large leaves; one of them, *C. sativa*, is called the sea-side grape, because it yields eatable fruit. Some of them grow well in our stoves and are increased by cuttings.

**COCULUS** (Boschin). A genus of East-Indian climbers belonging to *Hexandria Trigynia*, and to the natural order *Menispermææ*. Generic character: calyx of from three to six bractea-like sepals; corolla of three or six petals; nectarium of six scales; stamens opposite the petals; filaments awl-shaped; anthers two-celled. Fruit drupaceous one-seeded berries. The *C. indicus* is a well-known drug, and forms a considerable article of commerce, and for one purpose or other is used in great quantities in this country. Its hot acrid quality is useful in medicine; and it is said that it is also used by the compounders of stimulating liquors. Several of the species are kept in our hothouses, and propagated by cuttings.

**COCHINEAL FIG** is the *Opuntia cochimilifera* of Haworth. It is an icosandrous plant, and belongs to the natural order *Opuntiææ*. This opuntia is a native of South America, and the plant on which the coccus insect is found, and when collected and dried, forms the famous cochineal dye. For this purpose it is extensively cultivated in its native country, and has been carried to other parts with a view to the introduction of the insect also, but with only partial success. The plant is easily transported, as we have already had occasion to state. It grows well in our greenhouses, and no plant is easier propagated, as every joint of the stem will strike root if kept in dry earth.

**COCHLEARIA** (Tournefort) is the scurvy grass of English herbalists. It belongs to *Tetradynamia*, and to the natural order *Cruciferaæ*. The *C. armoracia*, or horse-radish, is a well-known and extensively cultivated condiment in cookery, and is perhaps as profitable a crop as can be grown by the market gardener. A piece of ground judiciously planted with horse-radish yields in the third and fourth year afterwards a vast number of marketable roots.

As the under-ground stem is the only useful part of the plant, the object of the cultivator is to have this as large and long as possible. The most common and successful method is trench planting, and which is performed in the following manner: the ground to be planted is divided into parallels, marked by the line and spade, two feet wide each. The earth of the first trench is dug out and thrown or barrowed to the opposite side to fill up the last. The sides of the trench should be worked upright, and to

the depth of full sixteen inches. The bottom should be broken up either with spade, fork, or mattock. On this, when duly levelled, two rows of sets are to be placed six inches from each side of the trench, which will leave a twelve-inch space between the rows. The sets may be put six or eight inches apart in the rows, and when the first trench is thus planted, it is filled with the earth from the second, breaking it well as it is thrown on the sets. The second trench being thus opened, the bottom stirred, and planted similar to the first, is filled with the earth from the third, and so on to the end.

The sets are inch-pieces of old roots. Some writers advise the crowns only to be chosen; these are certainly to be preferred, but any sound part of the root, whether great or small, will do for sets. From each set a single shoot is produced, and which after two or three years' growth is fit for use. As the shoots rise in rows one foot apart, they should be carefully taken up one after another, beginning at the first. In doing this it is usual to replant the vacant ground as the digging up proceeds, so that the plantation may be kept constantly furnished and productive; for as the spot chosen for the growth of horse-radish in private gardens is always some bye corner of the garden or orchard, it is seldom necessary to change its place.

Horse-radish may also be planted by a dibber of sufficient size and length, after the ground is trenched. The holes are made by line, and the sets dropped in, pressed to the bottom, and covered with fine sifted earth. Another mode of culture is by planting crowns or sets in shallow trenches, and earthing up the plants by covering them over eight inches deep in the winters of the second and third years; by this plan very large stems are obtained. There is yet another simpler method sometimes practised. The sets are dibbed on the surface of prepared ground; these produce a strong descending root, which in the second or third year is large enough for use.

Horse-radish seldom produces perfect seeds, because the principal energy of the plant is directed to enlarge the root, it being a law of vegetation that when seeds are produced plentifully the root is diminutive, and *vice versa*. Planting may be done any time during winter or spring; and as the leaves do not appear till near midsummer from deep planted sets of new plantations, it is usual to take a spring crop of radish, lettuce, or spinach, off the ground before the horse-radish comes up.

**COCHLEOCTONUS** (Meilzinsky). A genus of coleopterous insects, belonging to the section *Pentamera*, nearly allied to the glow-worm family *Lampyridæ*, and established for the reception of the large wingless and unwieldy females of the long previously established genus *DRILUS*, which see.

**COCHLOSPERMUM** (Kunth). A genus of lofty trees found in Mexico and India. Linnæan class and order *Monadelphæa Polyandria*, and natural order *Ternstræmiaceæ*. Generic character: calyx first in five parts, afterwards very much divided; stamens inserted in the receptacle; seed-vessel a utricle, containing one seed. These trees were considered by Linnæus and Willdenow to belong to the genus *Bombax*, from the East Indian one producing a substance like cotton, hence it received the specific name of *Gossipium*.

**COCKCHAFER**. A common insect, being the *Scarabæus melolontha* of Linnæus, or the *Me-*

*lontha vulgaris* of modern authors. See **MELOLONTHIDÆ**.

**COCKROACH**. A well-known domestic, disgusting insect, systematically distinguished under the name of *Blatta orientalis*. Full details of its habits will be found under the article **BLATTIDÆ**.

**COCKS'-FOOT GRASS** of agriculturists is the *Dactylis glomeratus* of Linnæus. It is a strong-growing British grass, and is always chosen as one of those to be sown in forming permanent pastures. It is next to the rye-grass for earliness, and having strong roots, produces a thick tuft of succulent leaves, very suitable for early lambs.

**COCKSPUR THORN** is the *Cratægus crusgalli* of Linnæus. It is a North American plant, and has long been cultivated in this country as a shrubby ornament. There are four or five varieties in nurseries, and, like all the genus, admired for their snowy blossoms in May. They are mostly propagated in this country by grafting on the common whitethorn.

**COCOON**. The envelope of silken or other materials, formed by the larvæ of many insects, immediately previous to their assuming the pupa or chrysalis state. Perhaps in no department of our knowledge of the lower tribes of animals, is there so much skill, or so much of that faculty which we term instinct displayed, as in the proceedings which characterise the formation of these envelopes. All larvæ, however, do not make these coverings, the cause of which is at once obvious; the pupa of the grasshopper or cockroach, dragon-fly or cixid, is an active animal, continuing to enjoy all the habits of the larvæ, and consequently not needing any other defence than it possessed in its former state, but in other insects the case is entirely different; the pupa state being one of inactivity and total helplessness, and in which the insect is consequently subject to the attacks of any stray bird or mouse, or not less voracious insect, which would feast with as much avidity upon the soft and creamy substance of the newly formed chrysalis, as the Romans did upon the cossus, which was a large insect in the earlier stage, and which is considered to have been the larvæ of the goat moth (*Cossus ligniperda*). Hence the necessity, not only for retreat to some quiet and unobserved corner or hole, but also for a covering for more complete concealment and defence. At this time many larvæ accordingly make their way several inches deep into the earth. Here, or concealed under leaves, moss, or other like matter, many insects become pupæ, with the mere precaution of fastening the substances which conceal them together with a glutinous secretion from the mouth; but others are far more careful, forming for themselves an entire covering, composed either of silk spun from their own mouths, or of silk united with the adjacent materials. Some few larvæ, however, as those of the ant-lion (*Myrmeleon*), and the lace-winged aphidivorous flies (*Hemerobius*), have the spinning apparatus placed at the extremity of the body.

Some cocoons are formed simply of a few threads, spun into an open work case, which permits the inclosed insect to be plainly perceived through the meshes; this is the case with the gipsy and satin moths (*Hypogymna dispar* and *Leucoma salicis*), &c. Such is also the case with the cocoons of some of the weevils and chrysomelidous beetles. The cream spotted tiger-moth (*Arctia villica*, see vol. i. p. 550), is more careful, forming a much closer cocoon, but

to M, as it had from E to I, and in this manner proceeds until it has nearly formed half its case, when turning round, it begins at the other end, and at length unites the two halves together, "thus inclosing itself," as Lyonnet says, "en une jolie cage" of network, which occupies only half an hour in the construction, but which is subsequently rendered much more firm by a strong layer of silk within.

The other instance which we propose to notice, is that of another small moth (*Microsetia ruficapitella*), the larva of which forms the curious lines of a brown colour, often to be noticed upon rose leaves, by eating away the internal fleshy part of the leaf, leaving the two surfaces entire. When full grown it eats its way out of the leaf, and crawls down the branches and stem, until it has found a convenient place to fix its cocoon, which is formed by stretching out its body, and attaching a thread to the branch; it then crosses its body to the other side, and there fastens it. By proceeding thus on all sides, keeping the hinder part of the body fixed, it forms the upper part of the cocoon, or that exposed to the weather, which is convex, and generally circular; the under part is oblong-shaped to hold the pupa, and much smaller than the upper, which projects considerably beyond it on all sides; so as to form a defence against the rain, somewhat after the fashion of a parasol. At one end the threads are not interwoven, and leave a space through which the pupa can force a passage. This remarkable cocoon is very flat, and at first of a pure white, but soon assumes a dark colour. It is formed towards the end of October, and the moth appears in the middle of the following May. It is an elegant little creature, the upper wings being gold coloured, with the extremity purple, and the head red. The expansion of the wings is nearly a quarter of an inch. E. W. Lewis in Entom. Mag., vol. i.

**COCOS** (Linnæus). A genus of palms, and certainly the most useful of all of them to the inhabitants of the countries where the trees naturally grow. Linnæan class and order *Monœcia Hexandria*, and natural order *Palmeæ*. Generic character: flowers androgynous, that is, male and female are on the same plant; calyx of three sepals; corolla of three petals; stigmas sitting; drupe fibrous, shell with three pores at the base; kernel equal in thickness, and hollow; embryo within the pores at the base.

This magnificent tree gives a peculiar character to the scenery of the country to which it is indigenous. The vast number of the trees crowded together, the height and equal diameter of their branchless stems, the spreading tuft of fronds which crown the head like an immense umbrella, together with the bunches of fruit suspended from among the footstalks of the fronds, forms altogether a spectacle the most imposing. The coast of the beautiful island of Ceylon, and that of Coromandel from Cape Comorin to Balasore at the mouth of the Ganges, is embellished with groves of cocoa-nut trees at shorter or longer distances from each other. To the voyager along these shores, the tree under notice is certainly the most prominent feature, and when he lands and enters a grove of them he feels astonished at their numbers and height.

The tree serves many purposes of the inhabitants. The regular form of the stem makes it easily convertible to the purposes of building, fencing, or the like; and though the grain is exceedingly porous and coarse, the wood is notwithstanding very durable. The leaves or fronds make excellent thatch for their

huts; the outer covering of the nut, after being macerated or soaked in water long enough to dissolve the pulpy cellular matter, leaves the mass of fibres, after some further preparation, fit for spinning into cordage, coarse wrappers for packing, and many other purposes. The shells are easily manufactured into various sorts of cups, &c., and converted into button-moulds, for which last purpose the substance is suitable, except that it discharges a brown colour when used on white or light coloured garments. When the nut is quite ripe, by opening one or two of the bottom pores, a fine pleasant flavoured fluid issues which is called "milk," and when the nut is split, a part not so fluid as the milk, nor so solid as the kernel, and easily scraped off with a spoon, is called the "cream," accounted a delicacy. Next follows the kernel, serving for more substantial food, and which many partake of as diet.

But the principal use of the tree to the inhabitants of India is the refreshing beverage drawn from it, and after fermentation drank under the name of "toddy." To obtain this, a part or the whole of the raceme of fruit is sacrificed. Soon after the fructification appears and begins to bend downwards below the fronds, the point is cut off, and to the stump is slung a pitcher-like vessel to receive the flow of sap from the wound. When one vessel is full it is replaced by an empty one, and this is continued so long as the sap flows freely. The place where this drink is manufactured is called by the English "a Toddy Tap," and where any one may be supplied with a draught on very low terms. The labourers who attend the bleeding of the trees have perhaps a score or two under the operation at the same time, so that considerable quantities are got together in a large vessel to be fermented at once.

This drink is most suitable for labourers and travellers in such a warm climate, for while it allays thirst it does not inebriate, a circumstance of no small advantage to the tippler, as almost all are inclined to be in that thirsty land. But here the art of the distiller is brought into action; an ardent spirit may be drawn from the toddy, which serves for other and far less sanatory purposes than merely quenching thirst.

Another valuable extract is procured from the cocoa-nut, namely, an useful oil, which is manufactured and sold at a reasonable price. The Cingalese, it is said, have a mode of extracting some nutritious matter resembling sago from the heart of the stems, but the process has not as yet been clearly detailed.

The cocoa-nut has the property of keeping sound for a long period; it has consequently been readily transmitted to every clime where it has a chance of succeeding. Already the West Indies and other warm parts of America possess the cocoa-nut in abundance, and from thence and other places Europe is supplied with the nuts in great plenty. It may here be asked, how do the almost naked natives manage to climb those lofty and branchless trees so readily? This is a very simple though expert manoeuvre. The climber first binds his ankles together with a soft bandage, the toes turned outwards, so that the hollow of each foot may cling to the circular surface of the tree. His head and upper part of his body is raised through a strong collar of rope which surrounds both the body of the tree and that of the man. This collar is rather slack and held on each side by the hands, the body being sustained by that part of the rope which passes round the climbers

loins. The first movement is leaning back on the collar and lifting the feet one step upwards, next by a sudden spring of the body towards the tree he jerks up with his hands at the same instant that part of the collar on the opposite side of the stem, by which he gains a higher hold. These alternate movements enables the climber to raise himself to the height of forty or fifty feet or more in a few minutes. The empty vessel which is slung at his back while he ascends is exchanged for the full one at top, and the last brought down to be emptied. The climber descends by reversing the movements he employed in ascending with considerable celerity and in perfect security. Without this mode of climbing it would be impossible to get either toddy or the nuts when wanted, applying ladders to such lofty trees is totally out of the question, for they could not be used in such woods.

The cocoa-nut plant is raised from the nut and kept in hothouses, but requiring much room are inconvenient in such collections.

CÆLIOXYX (Latreille). A genus of hymenopterous insects, belonging the division *Aculeata*, subdivision *Mellifera*, and family of the bees, having the scutellum bidentate, the wings with only two complete sub-marginal cells, and the body destitute of polliniferous organs; the abdomen, moreover, is of a conical shape (whence the derivation from the Greek of the generic name); in the males, also the extremity of this part of the body is toothed, and in the females it is cleft and gaping. From the want of organs for collecting pollen, these insects are evidently parasitic; indeed the Count St. Fargeau states, that it is chiefly in the nests of several of the woolly-bellied bees, *Megachile*, *Anthidium*, *Osmia*, &c., that, cuckoo-like, they lay their eggs. The genus, although containing not more than a dozen species, is distributed over the different parts of the world. They are often to be found on flowers. There are three or four British species, including the type, *Apis conica* of Linnæus, the female of which differs so much from the male, that it was considered by that author, as well as Fabricius, as a distinct species. It is of a black colour, with the abdominal segments margined with white.

CÆLOGYNE (Lindley). An orchideous genus from the East Indies. Linnæan class and order *Gynandria Monandria*; and natural order *Orchideæ*. Generic character: sepals distinct, spreading, the exterior ones oblongly egg-shaped, interior linear; labellum hollow, three-lobed, fringed, double crested, and articulated with the column; column kneed and winged; stigma two-lipped. This, like its congeners, has curious flowers, grows well in loose turfy moor earth, and does better in a frame or pit than in a house. It may be increased by division of the root.

COFFEA (Linnæus), is the tree which yields the fruit, of which the favourite beverage, coffee, is made. Linnæan class and order *Pentandria Monogynia*; natural order *Rubiaceæ*. Generic character: calyx small and five-toothed; corolla funnel-shaped; throat naked; stamens protruding; stigma divided; berry two-seeded. This celebrated plant is named from a place where it grows spontaneously, namely, near the town of Caffa, in Arabia. It is now extensively cultivated in many of the European colonies, both in the East and West Indies; and indeed in every climate suitable to its growth. The tree is middle sized, of a light regularly branched habit,

and formal outline. The berries are collected by hand, dried, and manufactured till fit for use. The coffee plant thrives well in our stoves, and if allowed plenty of pot-room and water, with the necessary temperature, flowers and fruits abundantly. It is increased by cuttings, which, according to Mr. Sweet, come into flower sooner than seedlings.

COLCHICUM (Linnæus), is the meadow saffron of English writers. It belongs to the sixth class and third order of the sexual system, and to the natural order *Melanthaceæ*. The meadow saffron or colchicum are bulbous rooted plants, and found in many parts of Europe. Their flowers have a strong external resemblance to those of the crocus, though they differ much in botanical character. One is a native of Britain, producing the flower in autumn, and followed by its large foliage in the spring. They are chiefly met with in meadows of diluvial soil; but are not esteemed by farmers as a pasture plant, from the supposition that the leaves are injurious to dairy cows. A powerful medicine is prepared from the bulbs. The garden varieties and species are increased by seeds or offsets.

COLEOPTERA (Aristotle, Linnæus; ELEUTHERATA, Fabricius). An order of insects of very great extent, having the wings inclosed in a case, composed of a pair of scaly pieces, meeting along the back in a straight line. The wings themselves are of a large size, and of a membranaceous texture, and when unemployed are shut up in several transverse folds, the first of which occurs beyond the middle. These scales are termed elytra, and shutting upon the back, they conceal the upper surface of the abdomen, as well as the wings, from view. The insects themselves are for the most part known by the name of beetles, although the term is not exclusively applied to them. Thus the blister-fly (*Cantharis*) is a coleopterous insect, as well as the turnip-fly (*Haltica nemorum*). If we examine a butterfly, a bee, or a dragon-fly, we shall at once perceive that the elytra of the latter do not exist as such, but that their place is occupied by a pair of large wings, of similar consistence with the following, and being equally with the latter destitute of folds. Comparing these insects with any coleopterous insect, as for instance a cockchafer, it will be easy to perceive the latter distinguished by the following character. *Wings two, membranaceous, folded transversely beneath two horny elytra*, which character precisely corresponds with the Greek name *Coleoptera*, and the Latin one of *Vaginipennes*, given by the Latin naturalists to these insects. As, however, we attend to more minute differences of structure, we perceive the necessity of still more rigorously fixing the limits of our groups, by the employment of other characters, without which we should confound the locust, the grasshopper, the cicada, and the cimex, with the coleoptera; and indeed in the early works of the great Swede, Linnæus united the two former insects, together with the generality of those which form the modern order of *Orthoptera*, with the beetles. And even in his last work, we still find the earwig united with them, although the others were separated to form the ill-assorted order of *Hemiptera*, which order Linnæus had at first well defined, to comprise only those species which have an elongated tubular rostrum, articulated and bent beneath the breast. Now the coleoptera, as well as the orthoptera, differ from these in having the mouth formed of jaws and other organs for mastication. If therefore to the

above character we add, *mouth with jaws*, all doubt as to the admission of the hemiptera is removed. An attentive comparison of the wings and wing covers, would unquestionably have led to the same result; but that now mentioned is not only much more simple and uniformly existent, but is also evidently dependent upon much more important considerations than the form of the wings and elytra. In like manner the differences existing between the oral organs of the coleoptera and the orthoptera might be resorted to, but another and more important character is at hand. Thus the orthoptera, in their passage to the perfect state, undergo no other change than the casting of the outer skin, and the gradual development of organs of flight, whilst in the coleoptera the metamorphosis is complete, and the pupa state quite inactive. Hence by the addition of the character, *metamorphosis, or rather pupa, incomplete*, we have three leading characters, which will not only separate the coleoptera from the fly, the butterfly, the cimex, &c., but also from those insects which have been by some authors united therewith. It is to be observed, however, that the first of the above characters does not exist throughout the entire order; thus in certain, although few instances, both wings and elytra are entirely wanting, as in the glow-worm and the female drilus; in others the elytra, though existent, are soldered together without any wings being concealed by them, as in many of the *Carabidae*, *Blapsidae*, and other terrestrial darkling beetles, which have no use for wings. There are in like manner to be found exceptions to the transverse folding of the wings, in the *Buprestida* and some of the longicorn beetles, whilst in *Meloe* one elytron partly laps over the other, and in *Sitaris*, *Rhipiphorus*, &c., the suture is not straight, the elytra not shutting together, whilst in *Atractocerus*, *Molorchus*, &c., the wings are not covered by the wing covers, from the reduced size of the latter. Still there are sufficiently strong indications of direct affinity between all these insects, and others belonging strictly to the order, so that it is impossible not to perceive that they equally belong to it, although they form exceptions to one out of several of its leading characters.

Scarcely any branch of natural history has been so much investigated as this order of insects; indeed many students, as well as amateurs, have exclusively devoted themselves to this group. The amazing variety of form; the richness or agreeable disposition in their colours; the great number of modifications which their external organisation presents to our view, and which consequently afford so many additional aids towards their classification; the circumstance that these animals generally surpass in size the remainder of the class to which they belong, and the ease with which they are preserved, owing to the greater consistence of the outer covering, all tend to render the coleoptera interesting to the student; but to these circumstances may be added the vast extent, as regards the number of species contained in the order. It would, indeed, be difficult correctly to judge of the number of these insects, distributed over the surface of the globe, each arrival from foreign climes bringing hosts of novelties to our cabinets; and not only is it from the little frequented countries either of the old or new world that these importations are derived, but every year adds considerably to the lists of our indigenous species, by the discovery of undescribed beetles. Many persons have hence been

induced to believe, that a new creation was constantly going forward, or that from the admixture of species, hybrids were produced. The latter is a difficult question to solve, but analogy, derived from well authenticated and long known species, induce us to object to such an idea. In order to account for this introduction of novelties, it is to be noticed, not only that the number of actual collectors of insects is wonderfully increased, as well as the modes of collecting greatly improved; moreover, in all our large maritime and commercial towns, the productions of foreign climes are to be found in great abundance, and with them are evidently introduced an immense number of wood, plant, or grain-feeding insects, which in favourable circumstances multiply and become acclimated amongst us; hence it happens that the vicinity of large towns exhibits a richer list of species than more thinly peopled districts.

It is however unquestionable, that the coleoptera exceeds in point of number of species, any other order of insects, although the diptera and hymenoptera, now that more attention is being bestowed upon the minute species, are not far behind the beetles in point of numbers. The French collections are estimated to contain not fewer than 30,000 distinct species of coleoptera, and it is by no means improbable that at least 20,000 more are contained in the cabinets of other countries, wanting in the former. Thus 50,000 species may be considered as actually existing in our collections; and when it is known that immense tracts of country in Asia, Africa, North and South America, New Holland, and the Islands of the Southern ocean exist, from which not a single insect has been received, we may without exaggeration conclude that there are from 100,000 to 150,000 species of beetles in existence. This number, however, will scarcely be considered overrated, when it is further mentioned that in our own little island upwards of 3,500 native species have been actually described.

In the series of insects the coleoptera also seem to possess a certain degree of superiority, which places them in the foremost ranks of the class to which they belong. An eminent French naturalist, M. Marcel de Serres, has not indeed adopted this opinion; the orthoptera, whose anatomy he has profoundly investigated, being in his ideas entitled to be placed at the head of the class, his opinion being founded upon a consideration of the superior development of the locomotive organs. Latreille however has considered that too much weight has been given to this character, and has suggested, from a general consideration of their comparative anatomy, that the coleoptera are the most perfectly organised of insects, and consequently as being entitled to the highest rank.

We will now proceed to give a rapid sketch of the external anatomy of these insects. The body consists of the head, a large segment which has been generally termed the thorax, two short inconspicuous segments which support the wing covers and wings, and the two posterior pairs of legs, and which form a portion of the true thorax; and lastly, a continuous series of rings which compose the abdomen, and which are not furnished with locomotive organs. The head is generally of a rounded form, furnished with a pair of antennæ, extremely varied in their form in the different families, but which in the majority consist of only eleven articulations; they often differ in the sexes,

those of the males being larger, longer, or laterally more developed than in the other sex. The eyes, which are always composite and faceted, are generally larger and globular in the carnivorous species, as well as in those which, from the slowness of their habits, have great need of defence against their enemies. Some species have been asserted to possess the simple eyes (*ocelli*), observed in the hymenoptera, &c.; but Latreille does not consider that any species possesses these organs; and indeed, as he is induced to suppose from a comparative examination of the eyes of insects, that the presence of these ocelli is an indication of optical weakness, their non-existence in the coleoptera seems to confirm his opinion of the superiority of these over other insects. The mouth consists, as in all masticating insects, of an upper lip (labrum, *a*), a pair of horny jaws moving horizontally (mandibles, *b*), two other jaws (maxillæ, *c*) of a less firm consistence, but more complex in their organisation, bearing a palpus (*d*) or feeler, and furnished moreover with a lateral lobe, which occasionally assumes the appearance of an additional palpus, and lastly a lower lip (labium, *e*), furnished with a pair of palpi (*f*), and implanted upon a broad horny basal piece, which is termed the chin or mentum (*g*).

The thorax, as usual, consists of three segments, but the first of them, or the prothorax, is so much developed at the expense of the second and third, that the only conspicuous part in the meso-thorax (or second segment), is the part usually termed the scutellum, whilst the meta-thorax (or third segment) is reduced to a short and almost obsolete ring, giving support to the pair of wings and the third pair of legs. The legs articulate with the posterior extremity of the segments, to which they are attached beneath, by means of a short piece termed the trochanter, which in the hind legs is more voluminous, forming indeed, occasionally, a large plate, sometimes moveable, but at others soldered to the segment, of which it appears to form a part; indeed in the water beetles, the large trochanters of the hind legs have been mistaken by some of our first entomologists for the sternum; this piece is followed by another small joint, the coxa, which is succeeded by the femur or thigh, which is the strongest part of the leg, and the tibia or shank, a piece generally of nearly equal length with, but more slender than, the preceding, the last portion of the leg consisting in an articulated piece called the tarsus, the number of articulations of which varies from three to five. The abdomen is attached to the meso-thorax by its entire breadth, its inferior portion or the belly being always more solid in its consistence than the upper surface, owing to the latter being defended by the wing covers; it is moreover provided on the under side with only six segments, whilst on the upper seven or eight are visible. In some insects, however, as the rove beetles (*Brach-*

*elytra*), which have the abdomen for the most part exposed, the upper surface is as firm as the lower. The additional segments of the body, two or three in number, which are to be observed in the body of the larva, compose, in the perfect beetle, the organs of generation.

The metamorphosis of the coleoptera, or rather its character, as derived from the state of the pupæ, is termed incomplete. The larva resembles a soft fleshy worm, having the head and upper surface of the thoracic segments scaly, and provided with six legs, attached in pairs to the three anterior segments of the body. The head of the larva exhibits, in an undeveloped manner, nearly all the parts of the mouth of the perfect insect. In the place of the faceted eyes, are to be seen a number of small granular tubercles, which somewhat resemble the ocelli of the hymenoptera, &c., being often six in number on each side of the head. The jaws are much more developed than the other parts of the mouth, which is doubtless owing to the circumstance, that it is in the larva state that the greatest supply of nourishment is taken by the insect. The antennæ are very small and conical, and generally only four-jointed. The more inactive and concealed these larvæ are, the more they exhibit the appearance of a worm; those of the more carnivorous species are generally more alert, and in the rove beetles we have seen that they exhibit very much of the appearance of the perfect insect. The extremity of the body of these larvæ is often furnished with a fleshy retractile tubercle on its under side, which is employed as a seventh leg. When the larva has attained its full size, it generally burrows into the earth, where it hollows out an oval cell, within which it is transformed into an inactive pupa, of a uniform whitish colour, with the wings and legs folded upon the breast. The pupæ of some of the species are, however, naked, as in the *Chrysomelidæ*, whilst others, as *Clythra*, pass this state within the case which had served for their abode whilst larvæ. The duration of these transformations, the habitations and economy both of the larvæ and perfect insect, varies, as may well be supposed, in so extensive a group, in the different families and genera. Arrived at their last state, they possess their full degree of development, and now the reproduction of their kind is their chief employment.

Compared, however, with many other tribes of insects, as for instance the bees, ants, wasps, ant-lions, &c., none or but very few beetles present in their habits any of those extraordinary traits of instinct which have so much engaged the attention of observers in every age and country; still, however, even in this respect they are not without interest, as we have already seen in the articles *CICINDELIDÆ*, *COCCINELLIDÆ*, *CEBRAMBYCIDÆ*, &c., and as we shall have to show in many other instances.

Hardly any coleopterous insect has been employed in the arts; but it is questionable whether some of the species might not be rendered useful. The meloe and the coccinella emit from the mouth and eyes a gummy fluid of a fine yellow colour, which might be employed in painting. The former insect is of a large size, and sufficiently abundant for experiment, if some of our celebrated chemists would not think the subject beneath their notice. In like manner the *Mylabris*, *Cantharis*, or *Carabus*, might furnish an useful extract of a fine colour. We have already in our articles upon these insects given an account of their

medicinal properties. It is not improbable that many other species possess similar powers. Less useful but highly ornamental, the metallic coverings of many species may be and indeed have been employed in decorating various kinds of trinkets, giving an effect equal to that of gold or precious stones of every shade. By the Indians they are employed to decorate the head-dresses and necklaces, as well as for earrings, &c.; and we have seen, in a large warehouse in London, entire dresses decorated with the elytra of the *Buprestis chrysis*. The larvæ of the *Coccinellidæ* are eminently serviceable in checking the swarms of *Aphides*, whilst the *Silphidæ* and many other insects, by feeding upon decaying vegetable and animal matter, are active agents in keeping up the regular succession of changes in the creation.

The coleoptera have been divided in different manners by various authors. By Linneus the construction of the antennæ formed the character upon which the sections were established, but the distribution more generally adopted by modern authors is founded upon the number of joints in the tarsi, as follows:—

Sect. 1. *Pentamera*, all the tarsi having five joints.

Sect. 2. *Heteromera*, the four anterior tarsi having five, and the two posterior having only four joints.

Sect. 3. *Tetramera* of the French authors, having apparently only four joints in each tarsus.

Sect. 4. *Trimera* of the French authors, having apparently only three joints in each tarsus.

It is to be observed, however, with respect to the two latter groups, that there is a minute rudimental joint at the base of the terminal joint which has been overlooked, and which renders the names *Tetramera* and *Trimera* incorrect; still the general structure of the tarsus in these two groups is so well marked that we have not hesitated to adopt them; and, secondly, that the section *Dimera* founded upon an incorrect examination of insects supposed to have only two joints (the *Pselaphidæ*, see BRACHELYTRA) is equally incorrect, and consequently rejected.

COLIAS (Fabricius). A genus of lepidopterous insects belonging to the section *Diurna* and family *Papilionidæ*, or true butterflies, having the hinder wings extended beneath the abdomen, so as to form a kind of canal on which this part of the body rests, the claws of the feet are small and bifid, each having two equal sized hooks; the palpi are short and very much compressed; and the antennæ are terminated by an elongated conical club, gradually increasing to the tip. The anterior legs, which in some of the butterflies are of a small rudimental size, are here fully developed. The caterpillars are fleshy and cylindrical, without either tubercles or the fleshy forked tentacula which arm the neck of the larvæ of the genus *Papilio*. These butterflies, which formed portion of the Linnean section *Danaï candidi*, are more gaily coloured than the allied insects composing the genus *Pontia*, including the common white butterflies, being especially distinguished by the bright yellow or orange colour, which in a remarkable degree pervades the whole group, thus evidencing the curious fact of the prevalence of peculiar colours in peculiar groups of animals. The genus is likewise interesting on account of another peculiarity. "Several papilionaceous insects," observes Mr. Stephens, "are remarkable for their periodical or irregular appearance, and none more conspicuously so than the insects of this genus.

The cause of this interesting phenomenon appears inexplicable, its solution has baffled the inquiries of entomologists, and several speculative opinions have been advanced thereon. By some persons their sudden increase has been attributed to the previous failure of their natural enemies, the ichneumons and the soft-billed birds; by others to an increased temperature; others again suppose that their eggs lie dormant till called into life and vigour by some extraordinary latent coincidences. But all these opinions are mere conjectures, and they do not sufficiently clear up the difficulty, which is rendered more obscure from the fact that several of the insects, especially *Cynthia cardui*, appear constantly in some parts and periodically in others."—Illust. Brit. Ent. vol. i. p. 10. The genus is a very extensive one, as regards the exotic species, but great confusion has occurred respecting the English ones. Thus whilst Stephens gives four, Curtis admits only two. We will not enter into the points involved in the determination of these questions at issue, further than to mention that, besides several other minor points of inquiry, the limits of specific variation, as well as the geographical range of insects (two most interesting subjects), are both included therein.

COLIUS—Coly. A genus of birds, regarded as being wholly or chiefly granivorous, and as such ranged by Cuvier in the conirostral division of his great order *Passeres*. All the known species are African birds dwelling chiefly in bushes and thickets, and we are but little acquainted with their manners. The name signifies "little crow."

The characters are: the bill thick, short, stout, convex above, flat below, a little compressed towards the point, upper mandible lapping over the edges of the lower one; nostrils small, basal, lateral, round, partly covered with feathers, and pierced in the horny substance; feet of mean size, with four toes, three to the front, united to the first joint, external toe longer than the tarsus, the hind toe short and reversible, and the claws very crooked; the wings very short, the first quill merely rudimental, the second shorter than the third which is the longest in the wing.

These birds are confined to the tropical regions of the old continent, though they, or others very much resembling them, are also met with in Australia. Being bad fliers, and capable of only short flight, these birds seldom venture out of the shade of the trees, but prefer running along the branches, which they do with great dexterity. They are said to eat buds and fruits, and to refuse insects; and therefore they are very annoying to various kinds of cultivated fruits, and are attacked with great avidity by cultivators.

From the weakness of their wings, these birds are incapable of making long migrations, or proceeding to any considerable distance from the woods in which they have their principal residence and where they build their nests, as the structure of their feet is not well adapted for walking, any more than their wings are for flight. They live in societies, and every bush contains a considerable number of families which build their nests close to each other in the very centre of the bush, which is done to protect their young from birds of prey. The eggs are three or four in number, in each more of a reddish or brownish colour according to the species. When it is not nesting time, these birds repose perching; and it has been said that, in order to sleep the more soundly, they suspend themselves by their claws with their head

downwards, the descent of the blood to which stupifies them so much that against morning they are easily captured. It does not appear that there is much truth in this; for the vascular system of those animals which repose in an inverted position is always so contrived that they can bear that position without any injury. As many as eight species of these birds have been described, varying in length from about a foot to half that measure, and differing considerably in colours; but the particulars of them are too imperfectly known to be of much interest to the general reader.

**COLLETES** (Latreille). A genus of hymenopterous insects belonging to the section *Aculeata*, sub-section *Mellifera* or bees, and the family *Andrenidae* or short-tongued bees. The insects composing this genus do not live in society, and consequently there are no neuters; the basal portion of the lower part of mouth (*mentum*) is long, but the fleshy part at its extremity is short and bilobed, having two lateral fleshy and slender appendages; the upper wings have three complete submarginal cells, of which the second and third are of nearly equal size, each receiving a recurrent nerve, and the body is hairy. This genus of bees, of which there are three or four British species (including *Apis succincta*, Linnæus, the type of the genus), presents several interesting peculiarities both of structure and habits. In our first volume (see pp. 361, 362) the mouth of the hive bee is figured, the terminal parts of which will be seen to be of a very elongated form; but in the genus of bees now under consideration these parts are so very short that in this respect it much more nearly approaches the wasps than it does the bees, and accordingly Mr. Kirby places it at the commencement of the family. And here we may take the opportunity of correcting an error which unavoidably occurred relative to the figures above referred to. At p. 362 three views of the mouth of the bee are given in the progress of gradual extension. These should have been succeeded by the figures of the "bee's mouth" in p. 361, which represent the same organs still more completely extended, but which were accidentally misplaced, so as apparently to illustrate the structure of the mouth of the larva, after the description of which they are placed. In the left hand figure of the two last mentioned, the tongue and its various parts are more protruded than in figure 3, the different organs on the left side of the figure being laterally extended, whilst the right hand figure represents the mouth at its greatest possible extension.

The peculiarity above noticed in the structure of the mouth of the colletes, seems calculated, as Mr. Kirby well observes, in his invaluable monograph upon the English bees, to assist it in the construction of the membranaceous cells, which the wise Author of nature has instructed it to form for the reception of its eggs; an account of which, from the work of Reaumur, he introduced into his monograph, without, however, having been himself fortunate enough to meet with the nests. The author of this article has been more successful than Mr. Kirby, having more than once discovered the nests, and reared the colletes, and can therefore testify to the correctness of Reaumur's account. Our nests were, however, found in hot sandy banks, thus differing (perhaps from a difference in the species) from those observed by Reaumur. They make their nests, as the latter author informs us, in the earth that fills the vacuities of certain stone walls; some of

them choose a northern aspect sheltered by trees; these nests are cylindrical, and consist of from two to four cells, placed end to end, each of which is shaped like a thimble, the end of the second fitting into the mouth of the first; the cells are not all of an equal length, some being five, others only four lines long; their diameter is about two lines. The cylinder usually runs in a horizontal direction; but sometimes, from the intervention of a stone or other obstacle, it takes a different course, so that the last cell or cells form an angle with the first; it is distinguished by transverse bands of different colours. The cells are composed of many layers of a very thin and transparent membrane; the red colour arises from the substance with which they are replenished, this is sometimes nearly liquid, at others it is merely a paste made of pollen and honey. After the larva is hatched, it soon imbibes all that is liquid, and when arrived at its full dimensions, it quite fills its cell; it resembles the larva of the hive bee. Whence these bees procure the membrane with which they form their cells, our author could not ascertain, but he conjectures it to be a secretion of the insect, analogous to that used by many others for similar purposes. Grew, in his *Book of Rarities*, gives the history of a bee supposed to belong to this genus, from the similar nature of the cells, which he says are admirably placed for warmth and safety, &c., lengthways one after another, in the middle of the pith of an old elder branch, with a thin boundary betwixt each bag; whilst Willoughby seems to have noticed their nests in similar situations to those which we have found, namely, in sand banks; where he says they burrow, making holes like worm holes.

**COLLINSIA** (Nuttall). A genus of handsome annuals, natives of America. Linnæan class and order *Didymamia Angiospermia*, and natural order *Scrophularinæ*. Generic character: calyx bell-shaped, five-cleft, persisting; corolla personate, back of the tube gibbous; upper lip erect and cleft, the lower one trifid, the middle division forming a hollow keel; stamens bent downwards, in the hollow of the corolla; anthers placed parallel; style two-lobed; capsule two-celled, four-seeded, and four-valved. These are elegant plants, and if seeds are procured may be treated like hardy annuals. If sown in the autumn, they will flower early and ripen seeds in the following summer.

**COLLINSONIA** (Linnæus). A genus of tall growing herbaceous plants, belonging to *Diandria Monogymia*, and to the natural order *Labiata*. Being hardy, they grow in any common garden soil, affecting a moist situation, and are increased by dividing the root.

**COLOCASIA**. The specific name of a large Egyptian arum, cultivated in that country for its tuberous roots. It is common in our hothouses as an ornamental plant, the leaves being large and handsome.

**COLOUR** is one of the external characters, by which all objects, whether animate or inanimate, may be distinguished; therefore in every department of natural history, it is an important element in classification and description.

In zoology the species and varieties of many animals are principally determined by the colour or colours which they exhibit; in botany, notwithstanding the influence of climate, change of seasons, soil, situation, and other incidental circumstances, every species of

plant has naturally determinate colours, by which it may be recognised; and in mineralogy, each species of mineral presents a particular colour or suite of colours, by which it may also be identified. In meteorology, the aerial tints, the meteors, and the atmospherical phenomena peculiar to certain countries, can only be appreciated by a correct perception of the different colours which characterise their appearance; while in hydrography, a similar power of discrimination is necessary, to describe the varieties of colour which occur in the seas, lakes, and rivers, which adorn while they fertilise the surface of the earth. Hence every naturalist should be well acquainted with the philosophy of colours; he should be able to discriminate them accurately; he should know the effects which their several combinations will produce; and should understand the circumstances by which they may be modified or entirely changed.

The colour of all natural bodies, whether we contemplate the gorgeous hues of sunrise or sunset, the iridescent plumage of a bird, or the tints that variegate the petals of a flower, must be derived either from the light of the sun, or else be inherent, like any other property of matter, in the substance of the bodies themselves, the light in that case being only the passive medium through which their effect is communicated. The majority of philosophers concur in ascribing their origin to some change in the constitution or condition of light, yet their opinion concerning the manner in which this change takes place, must depend entirely on the views they entertain concerning the nature and properties of light. On this subject two theories are at present very ably maintained by their respective advocates; the one termed the Newtonian or molecular; the other the undulatory theory of light; each of which is signally ingenious and beautiful in detail, and alike supported by men of the profoundest mathematical skill. According to the Newtonian or molecular doctrine, light is presumed to consist of an infinite number of very minute particles of matter, which proceed in a continuous stream from the sun, or any other luminous body, and which, impinging on the nervous filaments of the retina, with such rapidity, as to allow of no sensible intermission of the impression they excite, induce the sense of vision. On the other hand, according to the undulatory hypothesis, light is supposed to consist simply in the undulations of an exquisitely subtle and elastic medium or ether, which pervades the whole universe. The waves of this medium, according to the impulse communicated to them by the action of what are called luminous bodies, reach the nerves of the eye and excite the sensation of sight, in the same manner as the sensation of sound is excited in the nerves of the ear by the vibrations of air. In the history of science, never perhaps were two theories proposed to explain the same phenomena, in which the evidence in favour of each appears to be so fairly balanced; yet to understand how either may be applied to explain the origin of colours, we must revert to certain properties of light which are immediately connected with this interesting investigation.

Whether the molecular or undulatory theory be adopted, light is observed to move in straight lines, until intercepted in its progress by passing from a medium of one density into a medium of another density; or until interrupted by impinging against

some semi-transparent or opaque body. In passing from air into water, the rays of light on entering the fluid are observed to deviate from their previous rectilinear direction; they appear to become bent, and this deviation from the straight line is called the refraction of light. Hence when an oar is immersed in water, it appears distorted on account of the rays of light by which it is seen being refracted or bent, on emerging from the water. The extent, however, to which the light deviates from the rectilinear direction varies in different media; thus, as the atmosphere which surrounds the earth, is denser in its lower than in its upper regions, the light of the sun, in passing from the rarer into the denser strata, becomes more and more bent or refracted; so that it descends to us in a vertical curved line, for which reason the moon and stars appear to us at a greater altitude than they really are; for which, in astronomical and trigonometrical observations, allowance is always made. The rays of light, however, are not refracted if they fall perpendicularly on the denser medium; hence the refraction becomes less as the sun approaches to the zenith, and increases as it descends towards the horizon; accordingly, in the blaze of noon the sun's rays are reflected with silvery and dazzling whiteness from the surface of the waters, whereas towards evening, as the sun gradually sets its rays, falling obliquely upon the waters, the waves become illuminated with all the beautiful prismatic colours of the refracted light. Again, when light impinges upon any solid body, it is either almost entirely transmitted through it, in which case the body is transparent, or it is reflected or driven back at a certain angle, just as a marble after striking against a wall is reflected, or driven off again; and this is what is termed the reflection of light. The surface of metals which are highly polished, or glass quick-silvered at the back to prevent the transmission of the rays, are the best reflectors; as are also all white surfaces. When the earth is covered with snow, and all objects are shrouded in the same wintry garment, the snowy crystals reflect the sun's light so vividly in all directions, as to excite acute pain in the eye, an inconvenience much complained of by navigators, who have endeavoured to explore the dreary solitudes of the Polar Regions. Even the Esquimaux, and other natives of those snowy wildernesses, are obliged to protect their eyes from this reflection of the solar rays, by a sort of wooden shade which is commonly worn among them. To these two properties—refraction and reflection—we owe the uniform diffusion of light through the atmosphere; indeed, had the atmosphere, instead of possessing regions of different density, consisted of an unlimited homogeneous medium, the sun, the moon, and the fixed stars, would have appeared to shine in a firmament of darkness; so exquisitely adapted is the air we breathe, and the sunbeam which illumines our path, to the general economy and beauty of the universe. There is yet, however, connected with air, water, and other media through which light may be transmitted, a curious property to be noticed; viz. when they are sufficiently dense, they absorb a great quantity of the light which enters into them; in other words, the light which falls upon such transparent media, is greater than the quantity which is either refracted or reflected, so that a portion in some way or other becomes suppressed or lost. For this reason, owing to the absorption of the refracted light,

objects become quite invisible at a certain depth below the surface of water. So also on the top of the Andes or Alps, many more stars are visible to the naked eye, than in the valleys or plains below; because their rays having to pass through a smaller extent of air, less of the light which they impart becomes absorbed. These facts are recognised, and different explanations of them proposed by the supporters both of the molecular and undulatory theory of light, and require to be remembered in studying the colours which different natural bodies assume.

It was known to the ancients, that the light of the sun might be so acted upon by different objects, as to exhibit a variety of colours; thus Aristotle ascribed the appearance of the rainbow to the reflection of the sun's rays on the falling drops of rain; and Seneca states, that if the sun shine through a triangular piece of glass, the colours of the rainbow will be displayed. Indeed the exhibition of colours by the prism had often been made previous to the time of Sir Isaac Newton; it remained, however, for that illustrious philosopher to examine the phenomena more critically, and deduce from his analysis, more definite and important inferences than had been previously attempted. His method of proceeding was simple, and may be readily understood. In the first place he darkened a room, admitting through a hole in the window-shutter only a small quantity of light, which was reflected upon the opposite wall. He then, taking the triangular piece of glass or prism, interposed it in the course of the sunbeam, and observed, that instead of being simply directed out of its course, and forming the same circular image which it had previously done upon the wall, an oblong image of the sun appeared, presenting seven different colours. This surprised him, and he states that it "excited in him a more than ordinary curiosity to examine from whence it might proceed;" accordingly, apprehensive that some unevenness in the glass or other incidental circumstance might have occasioned a deception, he repeated the experiment in a variety of ways, yet always with a similar result. He then began to think, that what appeared to be white light must in reality be composed of these seven different colours; to determine this more satisfactorily, he took another prism, and so adjusted it as to refract the light in a contrary direction, so that the primary or different coloured rays were again blended together, upon which the white light was reproduced. Hence he inferred, that what seems to be homogeneous white light, is a combination of seven different coloured rays,—red, orange, yellow, green, blue, indigo, and violet; and he then proceeded to examine these different colours separately. In so doing, he allowed each particular colour to fall on a second prism, and observed that when refracted it was not, as before, drawn into an oblong image, nor into any other colour, wherefore he concluded that each of the seven primary rays of light possessed a specific degree of refrangibility, and that there is an immutable correspondence between the refrangibility of each ray, and the colour it possesses. This comprehends what is meant by the different refrangibilities of the rays of light; for it was observed that the red was less refrangible than the orange; the orange than the yellow; the yellow than the green; the blue than the indigo; and that the violet was the most refrangible of them all. The different colours so exhibited form what is described as the solar spectrum; but it

is to be observed, that by Sir Isaac Newton's analysis no lines or boundaries between the different colours were perceptible; the colours appearing to be shaded off by imperceptible gradations into one another, and he determined their relative proportions by the individual length or spaces they occupied. It has since been ascertained by Dr. Wollaston, aided by Fraunhofer, that when the prism is perfect, and the light admitted through a very small aperture, the spectrum received on a sheet of white paper will exhibit the prismatic colours, divided by an indefinite number of dark and sometimes black lines, which in all spectra formed by solar light, preserve the same intensity and relative positions, so that they may be esteemed fixed points for ascertaining the refractive powers of different media. It is worthy however of observation, that they differ with the species of light employed, the spectra of the moon and brighter fixed stars, exhibiting lines peculiar to themselves. Furthermore, it appears that Sir Isaac Newton erred, in not observing that the relations of the coloured spaces must be considerably modified by the angular magnitude of the sun, or luminous body, or the aperture from which his spectrum was obtained; hence his proposition, "that to the same degree of refrangibility ever belongs the same colour, and to the same colour ever belongs the same refrangibility," proves to have been incorrect. The researches of Sir David Brewster have indeed effected a still further analysis of the solar spectrum. Taking advantage of the property which certain coloured media have, of absorbing one or more of the primary rays, this accomplished philosopher has succeeded in reducing the colours of the spectrum to three, viz. red, yellow, and blue; the orange in the spectrum of Sir Isaac Newton, he found to be occasioned by the mixture of the red and yellow rays; the green by the mixture of the blue with the yellow rays. His investigations appear to have established the following facts concerning the composition of the solar spectrum. 1. White light consists of three simple colours, red, yellow, and blue, by the combinations of which all other colours may be formed. 2. The solar spectrum consists of three spectra of equal length, beginning and terminating at the same points, viz., a red spectrum, a yellow spectrum, and a blue spectrum; all other colours in the spectrum are compound colours, each consisting of red, blue, and yellow light, in different proportions. 3. A certain quantity of white light, incapable of being decomposed by the prism, in consequence of all its component rays having the same refrangibility, exists at every point of the spectrum, and may in some points be exhibited in an isolated state.

However the number of colours in the solar spectrum may be thus reduced, the variety of effect produced by their blending with each other can scarcely be brought down to analytical computation. Hence Professor Powell observes, "That a question often asked as to the number of primary colours can only be answered with reference to the sense in which it is asked. If it be meant to apply to the number of tints distinguished in the spectrum, this will be a matter of individual judgment to different eyes. Newton distinguished seven, others four, others three, but perhaps most observers would admit that it is impossible to fix on any number, since the light appears to go through every possible shade of colour between the deep red and faint violet. If we understand the question as applying to the number of

definite points or rays, to each of which a different refrangibility belongs, their number must be considered as infinite. The general view now given of the constitution of light, according to the molecular theory, will enable us to understand the explanation it assigns for the different colours observed in nature.

The principle on which all bodies are supposed to derive their colour is briefly this, that the particles of which they are composed absorb some, and reflect other of the primary and different coloured rays which enter into the composition of white light. The red petal of a rose is presumed to absorb the six other coloured rays, and reflect only the red ray; the blue flower of the harebell to absorb the six other and reflect only the blue ray; and so on with all objects that reflect the different primary rays discoverable in the solar spectrum. Those bodies which reflect several of such rays appear of various colours; those which reflect them all appear white, while those which absorb them all appear black; and the absorption and reflection of the different coloured rays depends, according to the hypothesis of Sir Isaac Newton, on the magnitude of the particles of which the body is composed. Thus the azure colour of the sky is caused by the particles being very small; the green colour of vegetables depends on their being somewhat larger; "the green of vegetables," says Pemberton, one of the most perspicuous of Newton's commentators, "our author judges to be of the third order, partly from the changes they suffer when they wither, turning at first into a greenish or more perfect yellow, and afterwards some of them into an orange or red, which changes seem to be effected by their tinging particles growing denser by the exhalation of their moisture." The change of colour, therefore, which any plant, mineral, or other substance, may undergo, either from the action of light, heat, or vital or chemical changes, is presumed to depend on some alteration which takes place in the size of its component particles, which causes other of the primary rays to be reflected. Instead, however, of the mere size of the particles determining the inflection of one or more of the coloured rays, Sir David Brewster supposes that the particles of bodies, solid, fluid, or aeriform, have a specific attraction for the particles of light; if they exercise a simultaneous and proportional action over all the simple rays, then the body is colourless or transparent; if they exercise a specific attraction only over some of the simple rays, then the body exhibits a determinate colour from the reflection of the other rays, whether blue, yellow, or red. The colours produced by the refraction and reflection of these primary rays are especially observable in the rainbow, in solar or lunar halos, in the glaciers that crown the summits of the mountains in Switzerland, and at sunrise or sunset upon the surface of the ocean. Hence too the colour of the sky, the blue and violet rays being most refrangible are more copiously distributed through the atmosphere than the other rays, while the red rays being the least refrangible are not so frequently transmitted; on account, indeed, of their diminished refrangibility, the most favourable condition of the atmosphere for their refraction is obviously when the least vapour or moisture is suspended in it, and accordingly it is a popular observation that a red sky at sunset is a sign of fine weather the next day. In accordance too with what has been noticed concerning the disposition of certain media to absorb light, the air or vapours suspended in it are observed

often to absorb the red rays; hence the fiery aspect of the sky at sunrise or sunset, and the flame-coloured masses of clouds which are often seen dispersed even to the zenith.

But this is not all, for, independent of the colours of natural bodies thus arising from the absorption and reflection of the primary rays, Sir Isaac Newton referred the colours of the feathers of birds, the wings of insects, the scales of fishes, &c., to the same cause as the colours exhibited by thin plates. It was ascertained by Boyle, and afterwards by Dr. Hooke, that when substances which appear to be opaque are reduced into very thin layers they display the most beautiful colours. This may be familiarly exemplified by the bubbles of the essential oils, spirit of wine, turpentine, or soap and water, which, as they become gradually thin, exhibit the most varied and brilliant tints. So also is it with solid substances. Glass may be blown so thin, or mica split into such fine films, as to display the same lively colours; and on the same principle, the delicate filaments of a feather, the exquisitely fine membrane of an insect's wing, or very thin scales, exhibit similar radiant hues.

The colours, however, of the plates vary according as the rays of light fall upon them; when viewed obliquely, they are not the same as when viewed direct, for which reason the colours in the peacock's tail change as the bird changes the posture of its tail in respect to sight. Hence also the delicate plumage of the little humming bird displays the most exquisitely varied rainbow hues, so that when numbers of them are seen together flitting about a flower, or wantonly describing eccentric gyrations in the sunny air, the perpetual shifting of the colours, as the position of the bird varies, has a most dazzling and brilliant effect. The beautiful colours in the interior of shells are referrible to the same cause, as are also the colours of mother-of-pearl, which, when examined under a powerful microscope, presents a surface covered with minute striæ and parallel waving lines. The explanation of this phenomenon, given by Sir Isaac Newton, was this, that a portion of light is reflected from the upper surface of the thin plate, whether of glass or any other substance; and that the coloured rays are refracted from the adjacent under surface. According, however, to the modern theory, which ascribes the effect to the doctrine of interference, the light reflected from the second surface of the plate interferes with the light reflected from the first, and as these two pencils of light come from different points of space, they must reach the eye with different lengths of paths; and the resulting tint arises from the combination of the pencils.

The Newtonian molecular theory of light, therefore, refers the origin of colours, first, to the decomposition of white light, and the absorption of some, and refraction and reflection of one or more of the primary or different coloured simple rays; second, to the interference of light by very thin plates or fringes, the light in both cases consisting of subtle material particles emitted by luminous bodies.

According to the undulatory theory of light, a very different explanation is given concerning the origin and nature of colours; yet before stating the doctrine it inculcates, we may observe that all the properties and phenomena of light above referred to, its refraction, reflection, and absorption, are upon the undulatory hypothesis satisfactorily explained. As the undulations of the ether are propagated in a rectilinear

direction, on reaching a solid body, part of the undulations must proceed forward into the interstices of the body, and part, as from a new centre of motion, are transmitted back into the air; in the former case they are refracted, and the amount of refraction depends entirely on the diminished velocity of the propagation of the undulations within the refracting medium; in the latter they are reflected; furthermore, when light is absorbed, the ethereal waves are presumed to be broken and scattered in dispersed undulations through the interior of the body (Herschel); hence the ordinary properties of light may by either theory be explained; there are, however, certain phenomena, or appearances which light may be brought to exhibit, which are explicable only upon the undulatory theory, one in particular already adverted to is what is termed the interference of light.

It was shown by Arago and Fresnel, that when two diverging beams are made to cross at a very small angle, instead of giving rise to a double illumination at the point where they mix, they exhibit a space striped with alternate black and bright bands. Here, therefore, we have the paradoxical result of two conspiring rays of light, producing absolute darkness, which is inexplicable by the molecular or Newtonian theory; but which is a direct consequence of the theory of undulations, according to which it is obvious that when two waves, propagated from different origins, meet in such a manner that the hollow of the one coincides with the elevation of the other, and the elevation of the one with the hollow of the other, the two waves must obliterate or destroy one another. Accordingly, the point remaining at rest, where the antagonism occurs must appear dark, the agitation of the ethereal medium being necessary to affect our visual organs with the sense of light and colour. Upon this interference of light the beautiful phenomena of periodical colours, or those exhibited by thin plates, appear also to be dependent. In this case a new divergence is given to some of the waves, while others pass on unaltered.

According, therefore, to the undulatory theory, colour is an effect produced by the vibrations of the ethereal medium, which affects us when in undulation with the sense of light, and the difference of the colours so produced depends on the greater or lesser frequency of the vibrations, the whole scale of colours from violet to crimson lying between vibrations which are four hundred and fifty-eight million millions, and seven hundred and twenty-seven million millions in a second; a proportion it may be observed smaller than the ratio of undulations which takes place in the production of perceptible sounds. As in sound the pitch or note is determined by the frequency of the *aerial* pulses, so according to the undulatory theory the colour is determined by the frequency of the *ethereal* pulses.

#### 1. WHITE.

1. Snow white is the characteristic colour of the whites, being free of all intermixture it resembles new fallen snow. Animal, breast of black-headed gull; vegetable, the snow-drop; mineral, Carrara marble.

2. Reddish white (snow white, with a minute portion of crimson red and ash grey). Animal, egg of grey linnet; vegetable, back of the Christmas rose; mineral, porcelain earth.

3. Purplish white (snow white, with the slightest tint of crimson red and Berlin blue, and a very minute portion

Whichever of these theories be adopted, the naturalist should acquire the power of discriminating with accuracy the distinction between every variety of colour, however blended, otherwise his descriptions, whether of animals, vegetables, or minerals, will be imperfect. It is true, that the majority of mankind readily distinguish the more obvious colours, red, yellow, blue; but the combinations these may assume are so numerous, and the tints so delicate, that they cannot be adequately appreciated excepting by a practised eye. Hence an artist will perceive beauties in a landscape which escape the notice of an ordinary observer. It is desirable therefore that the naturalist should commence his studies by learning to distinguish accurately the different colours of natural bodies; he should apply to each of these a definite and correct term, expressing even the very shade it may present; and he should know how the simple and elementary colours may be so combined as to produce the succession of tints observable in shells and minerals, in the plumage of birds, the petals of flowers, and which bathe with beauty at sunrise or sunset the earth, the ocean, and the heavens. He will find that the colours which adorn the face of nature pass in suites into one another; nor can any thing be more exquisite than the effect produced by their blending together in mutual harmony. The eminent Werner directed his attention to forming a nomenclature of colour, which has been adopted by Professor Jamieson, and adapted to the study of botany, zoology, and meteorology, by Mr. Syme. The original suite of colours was by Werner fixed at seventy-nine; but finding the number defective when applied in the study of zoology and botany, it was extended by Mr. Syme to a hundred and ten. "The method of classification adopted by Werner was," says Professor Jamieson, "simple and elegant. He placed together all those varieties which contained the same principal colours in a preponderating quantity, and he then arranged them in such a manner that the transition of the one variety into the other, and of the principal into the neighbouring colours was preserved, so that by mere ocular inspection any person, accustomed to discriminate colours correctly, can analyse the different varieties of colour which occur in the mineral kingdom." In this system as improved by Syme, there are ten principal colours, each of which contains one that is called the characteristic colour; thus snow is the characteristic colour of white, velvet-black of black, Berlin-blue of blue, emerald-green of green, &c., and this characteristic colour is so placed in the scale that, ascending or descending from it, we may trace the colours which are connected by transition. The following is the improved nomenclature of the Wernerian system by Syme; it explains how the gradations of colour are produced, and illustrates them individually by reference to some animal, vegetable, or mineral\*.

of ash grey). Animal, junction of the neck and back of the kittiwake gull; vegetable, white geranium; mineral, arragonite.

4. Yellowish white (snow white, with a very little lemon yellow and ash grey). Vegetable, hawthorn blossom; mineral, chalk and Tripoli.

5. Orange coloured white (snow white, with a very small portion of tile red and king's yellow, and a minute portion of ash grey). Animal, breast of white owl, or screech owl; vegetable, large wild convolvulus; mineral, French porcelain clay.

6. Greenish white (snow white, mixed with a very little

emerald green and ash grey). Animal, vent coverts of the golden crested wren; vegetable, polyanthus, narcissus; mineral, calc. sinter (forms the transition of white into green).

7. Skimmed milk white (snow white, mixed with a little Berlin blue and ash grey). Animal, white of the human eye-ball; vegetable, back of the petals of the blue hepatica; mineral, common opal.

8. Greyish white (snow white, mixed with a little ash grey). Animal, inside quill feathers of the kittiwake; vegetable, white Hamburg grapes; mineral, granular lime stone.

## II. GREYS.

9. Ash grey the characteristic colour (snow white, with portions of smoke and French grey, and a very little yellowish grey and carmine red). Animal, breast of long-tailed hen titmouse; vegetable, fresh wood ashes; mineral, flint.

10. Smoke grey (ash grey, mixed with a little brown). Animal, breast of the robin round the red portion; mineral, flint.

11. French grey (greyish white, with a slight tinge of black and carmine red). Animal, breast of the pied wag-tail.

12. Pearl grey (ash grey, mixed with a little crimson red and blue, or bluish grey with a little red). Animal, backs of the black-headed and kittiwake gulls; vegetable, back of petals of purple hepatica; mineral, porcelain jasper.

13. Yellowish grey (ash grey mixed with lemon yellow, and a minute portion of brown). Vegetable, stems of the barberry; mineral, common calcedony.

14. Bluish grey (ash grey mixed with a little blue). Animal, back and tail-coverts of the wood pigeon; mineral, limestone.

15. Greenish grey (ash grey mixed with a little emerald green, a small portion of black and a little lemon yellow). Animal, quill feathers of the robin; vegetable, bark of ash tree; mineral, clay-slate wacke.

16. Blackish grey (ash grey with a little blue, and a portion of black). Animal, back of nuthatch; vegetable, old stems of hawthorn; mineral, flint.

## III. BLACKS.

17. Greyish black (velvet black with a portion of ash grey). Animal, breast and upper part of the back of the water hen; mineral, basalt.

18. Bluish black (velvet black, mixed with a little blue and blackish grey). Animal, largest black slug; vegetable, crowberry; mineral, black cobalt.

19. Greenish black (velvet black, mixed with a little brown yellow and green). Animal, breast of the lapwing; mineral, hornblende.

20. Pitch or brownish black (velvet black, mixed with a little brown and yellow). Animal, guillemot, wing-coverts of the black cock.

21. Reddish black (velvet black, mixed with a very little carmine red, and a small portion of chestnut brown). Animal, spots on the wings of the tiger moth, breast of the pochard duck; vegetable, berry of the fuchsia coccinea; mineral, olivine ore.

22. Ink black (velvet black, with a little indigo blue in it). Vegetable, berry of the deadly nightshade; mineral, olivine ore.

23. Velvet black (the characteristic colour of the blacks, colour of black velvet). Animal, mole, tail-feathers of the black cock; vegetable, black of red and black West Indian peas; mineral, obsidian.

## IV. BLUES.

24. Scotch blue (Berlin blue, mixed with a considerable portion of velvet black, a very little grey and a slight tinge of carmine red). Animal, throat of the blue titmouse;

vegetable, stamina of single purple anemone; mineral, blue copper ore.

25. Prussian blue (Berlin blue, with a considerable portion of velvet black, and a small quantity of indigo blue). Animal, beauty spot on wing of the mallard drake; vegetable, stamina of bluish purple anemone; mineral, blue copper ore.

26. Indigo blue (Berlin blue, a little black, and a small portion of apple green). Mineral, blue copper ore.

27. China blue (azure blue, with a little Prussian blue in it). Animal, rynchites nitens; vegetable, back parts of gentian flowers; mineral, blue ore from Chessy.

28. Azure blue (Berlin blue, with a little carmine red). Animal, breast of the emerald-crested manakin; vegetable, grape, hyacinth, gentian; mineral, blue copper ore.

29. Ultramarine blue (equal parts of Berlin and azure blue). Animal, upper side of the wings of small blue heath butterfly; vegetable, borage; mineral, azure stone or lapis lazuli.

30. Flax-flower blue (Berlin blue, with a slight tinge of ultramarine blue). Animal, light parts of the margin of the wings of devil's butterfly; vegetable, flax flower; mineral, blue copper ore.

31. Berlin blue (the pure or characteristic colour of Werner). Animal, wing feathers of the jay; vegetable, hepatica; mineral, blue sapphire.

32. Verditter blue (Berlin blue, with a small portion of verdigris green). Mineral, lenticular ore.

33. Greenish blue, the sky blue of Werner (Berlin blue, white, and a little emerald green). Vegetable, great fennel flower; mineral, turquoise, some fluor spar.

34. Greenish blue, the small blue of Werner (Berlin blue with white, a small quantity of grey, and a hardly perceptible portion of red). Animal, back of blue titmouse; vegetable, small fennel flower; mineral, iron earth.

## V. PURPLES.

35. Bluish lilac purple (bluish purple and white). Vegetable, blue lilac; mineral, lepidolite.

36. Bluish purple (equal parts of Berlin blue and carmine red). Animal, azure blue butterfly; vegetable, parts of white and purple crocus.

37. Violet purple, violet blue of Werner (Berlin blue, mixed with red and a little brown). Vegetable, purple aster; mineral, amethyst.

38. Pansy purple (indigo blue, with carmine red and a slight tinge of raven black). Animal, chrysomela Goettdingensis; vegetable, sweet-scented violet; mineral, Derbyshire spar.

39. Campanula purple, the characteristic colour (equal parts of ultramarine blue and carmine red). Vegetable, Canterbury bell, campanula persicifolia; mineral, fluor spar.

40. Imperial purple (azure and indigo blue, with carmine red, about equal parts of each). Vegetable, deep parts of flower of saffron crocus; mineral, fluor spar.

41. Auricula purple (plum purple, with indigo blue and much carmine red). Animal, egg of largest bluebottle or flesh fly; vegetable, largest auricula; mineral, fluor spar.

42. Plum purple, the plum blue of Werner (Berlin blue, with much carmine red, a very little brown, and an almost imperceptible portion of black). Vegetable, plum; mineral, fluor spar.

43. Red lilac purple (campanula purple, with a considerable portion of snow white, and a very little carmine red). Animal, light spots of the upper wings of the peacock butterfly; vegetable, red lilac, pale purple primrose; mineral, lepidolite.

44. Lavender purple, the lavender blue of Werner (blue red, and a little brown and grey). Animal, light parts of the spots on the under wings of the peacock butterfly; vegetable, dried lavender flowers; mineral, porcelain jasper.

45. Pale blackish purple (lavender purple, mixed with a little red and black). Mineral, porcelain jasper.

## VI. GREENS.

46. Celandine green (verdigris green and ash grey). Animal, *phalœna margaritaria*; vegetable, back of *tussilago* leaves; mineral, beryl.

47. Mountain green (emerald green, with much blue and a little yellowish grey). Animal, *phalœna viridaria*; vegetable, thick-leaved cudweed, silver-leaved almond, *actynolite* beryl.

48. Leek green (emerald green, with a little brown and bluish grey). . . . Vegetable, sea-kale, leaves of leeks in winter; mineral, *actynolite*.

49. Blackish green (grass green, with a considerable portion of black). Animal, many small insects; vegetable, dark streaks on the leaves of Cayenne pepper; mineral, serpentine.

50. Verdigris green (emerald green, much Berlin blue, and a little white). Animal, tail of the small long-tailed green parrot . . . mineral, copper green.

51. Bluish green (Berlin blue, and a little lemon yellow and greyish white). Animal, egg of the thrush; vegetable, under disc of wild rose leaves; mineral, beryl.

52. Apple green (emerald green, mixed with a little greyish white). Animal, under side of the wings of the green-broom moth.

53. Emerald green, the characteristic colour of the greens (equal parts of Berlin blue and gamboge yellow). Animal, beauty spot on the wing of seal-drake . . . mineral, emerald.

54. Grass green (emerald green, mixed with a little lemon yellow). Animal, *scarabeus nobilis*; vegetable, general appearance of grass fields, sweet sugar pear; mineral, ural, mica.

55. Duck green (emerald green, with a little indigo blue, much gamboge yellow, and a very little carmine red). Animal, neck of mallard; vegetable, upper disc of yew leaves; mineral, ceylanite.

56. Sap green (emerald green with much saffron yellow, and a little chestnut brown). Animal, under side of lower wings of orange-tip butterfly; vegetable, upper disc of leaves of the woody nightshade.

57. Pistachio green (emerald green, mixed with a little lemon yellow, and a small quantity of brown). Animal, neck of the eider drake; vegetable, ripe pound pear; mineral, chrysolite.

58. Asparagus green (pistachio green, mixed with much greyish white). Animal, brimstone butterfly; vegetable, variegated horse olive geranium; mineral, beryl.

59. Olive green (grass green, mixed with much brown). . . . Vegetable, foliage of the *lignum vite*; mineral, epidote olive ore.

60. Oil green (emerald green, mixed with lemon yellow, chestnut brown, and yellowish grey). Animal, animal and shell of common water snail; vegetable, nonpareil apple from the wall; mineral, beryl.

61. Siskin green (emerald green, mixed with much lemon yellow, and a little yellowish white). Animal, siskin; vegetable, ripe Colmar pear, Irish pitcher apple; mineral, mica, from the ural.

## VII. YELLOWS.

62. Sulphur yellow (lemon yellow, mixed with emerald green and white). Animal, yellow parts of large dragon fly; vegetable, various coloured snap-dragon; mineral, sulphur.

63. Primrose yellow (gamboge yellow, mixed with a little sulphur yellow, and much snow white). Animal, pale canary bird; vegetable, wild primrose; mineral, pale coloured sulphur.

64. Wax yellow (lemon yellow, reddish brown, and a little ash grey). Animal, larva of large water beetles; vegetable, greenish part of nonpareil apple; mineral, semi-opal.

65. Lemon yellow, characteristic colour of the yellow series of Werner (a mixture of gamboge yellow, and a little ash grey). Animal, large wasp or hornet; vegetable, shrubby goldlocks, fresh lemon peel; mineral, yellow orpiment.

66. Gamboge yellow, characteristic colour of thyme. Ani-

mal, wings of goldfinch, canary bird; vegetable, yellow jasmine; mineral, high coloured sulphur.

67. King's yellow (gamboge yellow, with a small portion of saffron yellow). Animal, head of the golden pheasant; vegetable, yellow tulip, cinquefoil. . . .

68. Saffron yellow (gamboge yellow, with gall-stone yellow, about equal parts of each). Animal, tail coverts of the golden pheasant; vegetable, anthers of saffron crocus. . . .

69. Gall stone yellow (gamboge yellow, with a small quantity of Dutch orange, and a minute proportion of honey yellow). Animal, gall stones; vegetable, marigold apple. . . .

70. Honey yellow (sulphur yellow, mixed with chestnut brown). Animal, lower parts of the neck of the bird of Paradise; . . . mineral, fluor spar.

71. Straw yellow (sulphur yellow, with much greyish white, and a little ochre yellow). Animal, some Canary birds; vegetable, oat straw; mineral, calamine.

72. Wine yellow (sulphur yellow, mixed with reddish brown and grey, with much more white). Animal, body of silk moth; vegetable, white currants; mineral, Saxon topaz.

73. Sienna yellow (primrose yellow, with a little ochre yellow). Animal, vent parts of the tail of bird of Paradise; vegetable, stamina of honeysuckle; mineral, pale Brazilian topaz.

74. Ochre yellow (sienna yellow, with a little light chestnut brown). Animal, vent colours of the redstart; . . . mineral, porcelain jasper.

75. Cream yellow (ochre yellow, mixed with a little white, and a very small quantity of Dutch orange). Animal, breast of teal drake; . . . mineral, porcelain jasper.

## VIII. ORANGE.

76. Dutch orange (the orange yellow of Werner is gamboge yellow, with carmine red). Animal, crest of golden crested wren; vegetable, common marigold; mineral, streak of red orpiment.

77. Buff orange (sienna yellow, with a little Dutch orange). Animal, streak from the eye of the king-fisher; vegetable, stamina of large white cistus; mineral, natrolite.

78. Orpiment orange, the characteristic colour (about equal parts of gamboge yellow, and arterial blood-red). Animal, the neck ruff of the golden pheasant, belly of the water newt; vegetable, Indian cress.

79. Brownish orange (orpiment orange, with a little hyacinth red, and a small quantity of light chestnut brown). Animal, eyes of the largest flesh fly; vegetable, style of the orange lily; mineral, dark Brazilian topaz.

80. Reddish orange (buff orange, mixed with a considerable portion of tile red). Animal, lower wings of the tiger moth; vegetable, hemimeris, buff hibiscus. . . .

81. Deep reddish orange (Dutch orange, mixed with much scarlet red). Animal, gold fish, lustre abstracted; vegetable, scarlet Lymington apple. . . .

## IX. RED.

82. Tile red (hyacinth red, mixed with much greyish white, and a small portion of scarlet red). Animal, breast of the cock bullfinch; vegetable, shrubby pimpernel; mineral, porcelain jasper.

83. Hyacinth red (scarlet red with lemon yellow and a minute proportion of brown). Animal, red spots of the lygæus apterous fly; vegetable, red on the golden rennetto apple; mineral, hyacinth.

84. Scarlet red (arterial blood red with a little gamboge yellow). Animal, scarlet ibis or curlew, mark on head of red grouse; vegetable, large red oriental poppy; mineral, light red cinnabar.

85. Vermillion red (scarlet red with a minute portion of brownish red). Animal, red coral insect; vegetable, love apple; mineral, cinnabar.

86. Aurora red (tile red with a little arterial blood-red and a slight tinge of carmine red). Animal, vent coverts of

pied woodpecker; vegetable, red on the naked apple; mineral, red orpiment.

87. Arterial blood red; the characteristic colour of the red series. Animal, head of the cock goldfinch; vegetable, corn poppy, and cherry . . . .

88. Flesh red (rose red mixed with tile red and a little white). Animal, human skin; vegetable, larkspur; mineral, heavy spar, limestone.

89. Rose red (carmine red with a great quantity of snow white and a very small portion of cochineal red) . . . . Vegetable, common garden rose; mineral, figure stone.

90. Peach blossom red (lake red mixed with much white) . . . . Vegetable, peach blossom; mineral, red cobalt ore.

91. Carmine red, the characteristic colour of Werner (lake red with a little arterial blood red). . . . Vegetable, raspberry, carnation, pink; mineral, oriental ruby.

92. Lake red, the crimson red of Werner (arterial blood red with a portion of Berlin blue). . . . Vegetable, red tulip, rose officinalis; mineral, spinel.

93. Crimson red (carmine red with a little indigo blue). . . . Mineral, precious garnet.

94. Purplish red, the columbine red of Werner (carmine red with a little Berlin blue and a small portion of Indigo blue). Animal, outside quills of torico; vegetable, dark crimson officinal garden rose; mineral, precious garnet.

95. Cochineal red (lake red mixed with bluish grey) . . . . Vegetable, under disc of the decayed leaves of none-so-pretty; mineral, dark cinnabar.

96. Venous blood red (carmine red mixed with brownish black). Animal, venous blood; vegetable, musk flower of dark purple scabious.

97. Brownish purple red, the cherry red of Werner (lake red mixed with brownish black and a small portion of grey). . . . Vegetable, flower of deadly night-shade; mineral, red antimony ore.

98. Chocolate red (venous blood red mixed with a little brownish red). Animal, breast of bird of Paradise; vegetable, brown disc of common marigold.

99. Brownish red (chocolate red mixed with hyacinth red and a little chestnut brown). Animal, mark on throat of red throated diver . . . . mineral, iron flint.

## X. BROWNS.

100. Deep orange-coloured brown (chestnut brown with a little reddish brown and a small quantity of orange brown). Animal, head of pochard; vegetable, female spike of cat's-tail reed . . . .

101. Deep reddish brown (chestnut brown with a little chocolate red). Animal, breast of pochard, neck of teal-drake; vegetable, dead leaves of green panic grass; mineral, brown blende.

102. Umber brown (chestnut brown with a little blackish brown). Animal, moor buzzard; vegetable, disc of rudbeckia . . . .

103. Chestnut brown, the characteristic colour of the browns of Werner's series (deep reddish brown and yellowish brown). Animal, neck and breast of red grouse; vegetable, chestnut; mineral, Egyptian jasper.

104. Yellowish brown (chestnut brown mixed with a considerable portion of lemon yellow). Animal, light brown spots on the guinea-pig, breast of hoopoe . . . . mineral, iron flint and common jasper.

105. Wood brown (yellowish brown mixed with ash grey). Animal, the common weasel, light part of feathers on back of snipe; vegetable, hazel nuts; mineral, mountain wood.

106. Liver brown (chestnut brown with a little black and olive green). Middle parts of feathers of hen pheasant and wing coverts of grosbeak. . . . Mineral, semi-opal.

107. Hair brown (clove brown mixed with ash grey). Animal, head of pin-tail duck.

108. Broccoli brown (clove brown mixed with ash grey and a small tinge of red). Animal, head of black-headed gull . . . . mineral, zircon.

109. Clove brown (ash grey mixed with a little blue-red and chestnut brown). Animal, head and neck of male kestrel; vegetable, stems of black currant bush; mineral, surface of rock crystal.

110. Blackish brown (composed of chestnut brown and black). Animal, stormy petrel, wing coverts of blackcock, forehead of fountart . . . . mineral, mineral pitch from Neufchatel, moor coal and bituminous wood.

The colours which may be thus recognised in the animal, vegetable, and mineral kingdoms, are liable to undergo many changes which appear determined by the influence of light, heat, change of seasons, climate, age, food, soil, and certain chemical actions to which all inert matter is constantly liable. It appears to be a provisional law that animals, subjected to be preyed upon by other animals, assume the colour of the soil or medium by which they are surrounded. Thus rabbits appear of the colour of the soil in which they burrow, and the colours of the scales of fish vary according to the colour of the river beds over which they swim. It has been shown by an intelligent naturalist that when perch, gudgeon, or minnows, are confined in water, the bottom of which rests upon different coloured soils, the scales of the fish gradually change their colour, and assimilate to that of the soil (Stark, in Jamieson's Journal, vol. ix. p. 329, 1830). A still more remarkable exemplification of this provisional law may be observed in the colour of the eggs of birds. Those birds whose nests and eggs are more exposed to the view of their enemies than other animals, lay eggs which are of the colour of the objects by which they are surrounded; thus the partridge, pheasant, and other birds which lay their eggs among grass without any regular nest, present us with eggs of a greenish colour, so that they escape the detection of rapacious birds; while those which nestle in holes, as the woodpeckers' wrynecks, water ouzels, and swifts, present us with eggs of a pure white, which, if exposed, would be immedi-

ately perceived by their enemies (Ibid, vol. viii. p. 130, 1829). The most curious fact, however, which the naturalist observes is the change of colour which plants and animals, under various circumstances, undergo. These too are often of singular contrast; thus the flower of the blue crocus frequently changes into yellow, the blue columbine to red, the blue violet to white. The changes too during inflorescence are often very remarkable; thus the flower-buds of the scorpion grass (*Myosotis palustris*) are delicate rose colour, but they turn to a bright blue as they open. It is well known that the plumage of birds, and the hair of quadrupeds, are subject to remarkable changes of colour, determined obviously by the influence of season, climate, age, food, and other incidental circumstances. As winter approaches, the ptarmigan begins to change colour, and gradually, about the month of February, becomes perfectly white. As the summer, however, returns, black spots appear upon the feathers, which gradually expand into a reddish brown until, in summer, the bird resumes its mottled brownish colour. The change of the human hair from a dark colour to grey or white is a matter of daily observation, and known to be caused by grief, and also by old age. The hair of the unfortunate Louis XVI. of France became quite grey during the night previous to his execution; so also, on the authority of Madame de Campan, did that of the unfortunate Marie Antoinette the night previous to her unhappy death. And to what are these changes of colour referrible? the explanation will depend entirely on the theory of

colour adopted. If we accept the Newtonian or molecular theory, we must conclude that some change takes place in the size of the particles of the bodies, whether hair, feathers, or flower petals, which causes an alteration in the absorption and transmission of the primary rays; thus in the case of the autumnal leaf, when no longer nourished by the usual circulation of the sap, its particles undergo a change which cause it to absorb the green rays which were before reflected, and reflect the red, orange, or red rays which were before absorbed. To this theory, however, Sir David Brewster does not assent; he considers it probable that these tints are caused by two different juices on each side the plant, which exert a different affinity over the primary rays. "The colours of vegetable life," he observes, "and those of various kinds of solids, arise, we are persuaded, from a specific attraction which the particles of these bodies exercise over the different coloured rays of light." As autumn therefore advances, we are to presume that the juices of the leaf change; there is a difference in the secretion, and consequently in the attraction of the primary rays. It must, however, be confessed that this is a mere hypothesis, it is overturning one theory by another equally undemonstrable, for where is the proof that any such affinity exists as is here supposed? Lastly, if we adopt the undulatory theory, we must conclude that the change of seasons, age, climate, &c. causes such a change in the particles of bodies as induces a greater or lesser frequency in the undulations of the etherial medium, now producing the violet and now the crimson colour.

However veiled in obscurity may be the laws of light and colour, the different colours which irradiate the world, are of eminent importance in the general economy of nature. The colour of different soils influences their fertility, the darker soils absorb, and the light reflect the solar rays. The varied shades of green presented by grass, herbs, and the foliage of trees, relieves the surface of the earth from a monotony which otherwise would have been painful to the eye. The gaudy plumage of birds in tropical climates protects them from the direct heat of the sun's rays, which are reflected from their feathers in brilliant rainbow hues. Animals, which are guided principally by the sense of sight, are attracted to their prey by the colour which now exposes and now conceals them from their view. The vulture perceives chiefly by its colour its prey at an almost incredible distance; and whales are attracted by their colour to the molluscæ on which they feed. The disposition, therefore, of the colours of natural bodies is in strict unison with that harmony of design which is manifested throughout the universe, and which reveals itself, especially to the naturalist, in every path he is tempted to explore.

COLTS'-FOOT is the *Tussilago farfara* of Linnaeus. It is a medicinal herb, and a very troublesome weed to the farmer of damp clayey land. The flowers come forth early in the year, and long before the large roundish leaves. Deep and repeated ploughings in the spring months is the only method of destroying the roots and preventing its spreading.

COLUMBER, a genus of ophidian reptiles, belonging to the division of true serpents which are not venomous; and exceeding in number any other genus of the order, and, indeed, every genus of reptiles. They are of course without fangs or moveable teeth adapted for inserting poison into wounds; and, therefore, they are either simply swallowing serpents, or

crushing serpents, according to their size and strength. They have large plates on the belly, and a double row of plates on the under side of the tail, by which they are readily distinguished from the poisonous serpents; but the number of species in the genus itself is so great, and the distinctions between some of them are so slight, that they can hardly be brought into any intelligible order without a degree of minuteness of detail, which is quite incompatible with the nature of a popular work; and which, though it could be accomplished, would be of little value to any but those who make this very difficult class of animals a particular study.

In disposition and habits they all very nearly resemble each other; but they differ greatly in size, in strength, and consequently in the sort of prey on which they live. Their head is generally flattened, of an elongated oval form, having the muzzle blunt and beset with a few tubercles; the head is covered with large plates, about nine in number. Their tongue is forked, and they move it with great celerity; and from this probably has arisen the vulgar notion of the tongues of serpents being darts with which they can inflict envenomed wounds; which notion, though it has found its way pretty largely into figurative writing, is of course, wholly without foundation. The lips of these serpents are usually covered with scales rather larger than those on the body. The teeth in the jaws are numerous, and generally much hooked, and they assist in the process of swallowing. In some of the smaller species the skin is very tender, but in the larger ones it is correspondingly strong. That of the head and throat, in particular, admits of great extension; but when the scales are removed, and it is tanned into leather, it is compact and thick, and very durable. The scales upon them all are imbricated, and generally speaking they are lozenge-shaped, and the marks of them give a very peculiar appearance to the tanned skin.

The whole of the genus are oviparous, and most of them deposit their eggs in the ground to be hatched by the heat of the sun. Those eggs are elongated ovals, with the ends of equal thickness, and covered with a whitish membrane about the consistency of parchment, which is flexible at first, but which hardens by exposure to the air. The young, while in the egg, floats in an albuminous fluid, something similar to that which surrounds a chick in the egg; and it is furnished with a true umbilical cord, which is attached to the belly a little in advance of the vent. All the species of this genus are understood to change their skins as is the general habit of serpents.

Both from their form, and the power and voracity of some of the larger species, these animals lie under the general denunciation which the civilised world appears to have pronounced upon the whole serpent tribe. Whether this arises from the metaphorical allusion to the serpent, as the symbol of temptation in the book of Genesis, it is of little consequence to inquire; neither is it worth while to go into a formal refutation of the vulgar notion that serpents walked on feet, before the catastrophe above alluded to; and that, in consequence of their deceitful conduct, they were subsequently doomed to crawl on their belly. We may just remark that a serpent is no more a mutilated creature than any other member of the animal kingdom; and that, all footless as they are, their powers of locomotion are, especially in many members of this genus, very efficient and also very

graceful. If we were to take the degradation of the serpent, in point of shape, in a literal sense, we would also require to take its feeding in the same. Now, the metaphorical denunciation against the serpent is, that it shall "eat dust" as well as crawl on its belly; and we know from observation, that there is no serpent whatever which subsists upon this species of aliment. By far the greater majority of serpents prey upon live animals of some description or other; and the part which they thus perform in wild nature is a very important one, especially in warm regions, where the production of small life is so abundant and so rapid, that, were it not for some such a race of beings as the serpents, the system of nature could hardly be carried on.

It may not be amiss, as tending in part to remove the obloquy under which this order of animals lies, and the horror which the vulgar have in general of them, to mention very shortly the meaning of the word "serpent" in the passage above alluded to. It means "self conceit," or a following of one's own appetites not only without any regard to right and wrong, but with a knowledge that the gratification of the appetite is not right; and the denunciation is directed not against any species of ophidian reptile, but against this figurative serpent—the corruption of the human heart, or the perverseness of human actions. "Upon thy belly shalt thou go," is the declaration of what we perceive every day to be true; namely, that they who once break through the laws of justness and propriety in the gratification of their bodily appetites, lose their intellectual character, and become the slaves of their own animal propensities, for the whole of which the belly is often used as a figurative and certainly a very appropriate expression. So also the eating of dust means nothing more than that those who thus degrade their intellectual nature, and become mere animals in habit, can have no possession, and no feeling of the value of any possession, except what is connected with gross material indulgences, the figurative name for which, is very often the dust of the ground; and this dust, in the sense in which it is thus used, is a very appropriate name—it means vegetable mould, or that species of earth which is most favourable to the growth of plants; and we need not add that this mould is the primary element in the support both of animals and of vegetables, the only substances which can gratify the appetites of man.

These remarks are not foreign to the subject in hand, because the genus coluber contains those serpents which are more generally distributed over the world, most numerous, most beautiful in their colours, and most disposed to remain near the habitations of man, and we may almost say absolutely court human society. Though they belong to different classes of animals, differ much in their forms, in their mode of production, and in their way of life, yet, if we take those differences along with us, we shall find that there is a considerable analogy between those serpents and the cats. They inhabit different kinds of places no doubt; and, generally speaking, they are better swimmers, and much more aquatic in their habits than the feline race, but they resemble these in the facility with which they glide through tangled places, and the certainty with which they capture small quadrupeds, birds, and other little animals, especially different kinds of mollusca, which would not leave a single green leaf in the more humid brakes of the warm latitudes, if it were not for the labours of these ser-

pents. Those places are very generally so close and tangled, that nothing but a serpent can penetrate them; and thus, though there are many large birds which ply diligently as scavengers in the tropical countries, they can only prey in places which are comparatively open; and thus, though they might and do pick up the dead bodies of those small animals, which are subject to casualties during the violence of the season, and also catch a good number of strays, they leave what may be considered as the nurseries of small animals wholly untouched; and thus the serpents become the true regulators of their numbers.

When we compare the species of this genus with each other, and take along with them the boas, which though they have distinctive characters in the systems of natural history yet very much resemble the colubers in their habits, we find that though there is not, strictly speaking, a polar race, as there is in the cat tribe, yet there is, as in these, an increase, both in numbers and in size and strength, as we approach those regions of the world where the action of life, both animal and vegetable, is at a maximum.

A very little reflection will suffice to convince the reader that there can be no species of serpent well adapted for inhabiting the land in the extremes of the polar countries. Serpents are covered with scales, which, even admitting that they are composed of the same materials as fur or feathers, are, from the very fact of their being in solid plates, while the others are loose and flocculent, much better conductors of heat. The consequence is, that serpents are capable of enduring only a limited range of temperature, in which respect they bear no inconsiderable resemblance to scaly fishes, and no attempted domestication would probably succeed in enabling a serpent to accommodate itself to difference of climates, or of seasons, to any extent at all comparable with that of which furred and feathered animals are capable; neither would it, perhaps, be possible to preserve them in a state of activity during those seasons of the year at which they are naturally dormant. We shall, however, be better able to notice those physiological characters of serpents which adapt them to different latitudes, and to peculiar localities, when we have the whole class before us in the general article OPHIDIA; therefore we shall only farther remark that in the north-west of Europe, the species of coluber are very rare, that they increase as we proceed southward and eastward, and probably extend farther into Siberia than they do into corresponding climates into western Europe. In those northerly places, however, the individuals are of small size; but in the Oriental Archipelago, they rival if they do not exceed the Boas of the American continent; and, though many of the stories told of them must be considered as exaggerated, yet it is certain that in Java, and the adjacent islands, they are very formidable animals capable of crushing deer and goats to death in their folds, and of swallowing an animal several times the diameter of their own body.

All the members of the genus are, indeed, remarkable for their capacity in swallowing. Their jaws, of which nearly a corresponding description will be found in the article Boa, are capable not only of opening till the whole gape is a plane, but of considerably more distension both ways, by means of the elastic cartilage which unites the different bones of the jaws. The smaller species subsist upon frogs, small lizards, mollusca, mice, and other little animals: And in

situations where they abound, and are not destroyed in consequence of the superstitious prejudice there is against them, they are useful in clearing the vicinities of houses of many troublesome creatures. They are also generally expert in climbing trees, and almost all of them are excellent swimmers. They are not absolutely aquatic, but they prefer moist situations; and the very large ones are seldom found at a great distance from the water.

There are some idle stories believed by the country people of those places where serpents of this genus are common, such as that they suck the milk of cows, whose mammae they reach by twining up their hind legs, and that by holding on with their teeth while they suck, they occasion disagreeable wounds. It does not, however, appear that there is any truth in these stories, any more than there is in the other allegations, that they are apt to creep into the mouths of persons who sleep in the open air near their haunts, and if they do not choke them by sticking in the throat, prove very disagreeable inmates of the stomach. This prejudice is a very old one, and we find it continued to the present day; and it has not always been confined to the mere vulgar, but was eagerly laid hold of by empirical practitioners in pretended medicine, during those periods of the history of that most extraordinary art, when it was not deemed necessary that the doings of the doctor should have any connexion whatever with physiology or with common sense, but that he had the better chance of success the more he was opposed to both.

That these animals are fond of creeping into holes is certainly true; but the mouth of a warm-blooded living animal is not the most likely lodging-place for them; first, because the temperature would be too high for them; and, secondly, because the gullet of an animal is the gate of death to everything which enters; and if it were possible to imagine that a savage could once get a tiger or a boa constrictor fairly down his throat, indigestion apart, he would feel no more trouble from it than from any dead substance. There neither is nor can be any living creature in the stomach of an animal, but such as can naturally breed there; and of parasitical animals (*Entozoa*) which are found in the alimentary vessels of other animals, the majority, if not the whole are found in the intestinal canal farther down than the true digestive stomach.

In temperate countries none of the colubers attain a very large size; but they are often very beautiful in their colours, and very lively and graceful in their motions. The sound of all their voices is a sort of hiss, sometimes very sharp, but varying considerably in tone in the different species. When the weather begins to get cold, they retire to their holes, where they remain dormant till the spring; and they are not much seen abroad even in the warmer months. In the warmer part of the season, indeed, they seem to require a good deal of exposure to the sun before they recover from their torpor; for then they are abroad and active in proportion as the weather is hot and sunny; but it should seem that, beyond a certain degree, the heat of the sun is not so favourable to them. This must, however, in no small degree, depend upon the nature of the climate, and the consequent adaptation of the species.

The number of species, and even of sub-genera, into which these reptiles have been divided, are so many, and have been so differently arranged by different authors, that the details of them would convey

no popular information. The simplest view that can be given of them is a division into four sub-genera: *Python*, *Hurria*, *Dipsas* and *Coluber*, properly so called, and it is the last of the sub-genera of which the species are so numerous, and many of which are natives of temperate climates.

**PYTHON.** This sub-genus very closely resembles the boa, except that the plates on the under-side of the tail are double, whereas those in the true boas are single. The largest species of this genus is the great coluber of the Sunda Isles (*Coluber Javanicus*), which is called "*Ular sawa*, or the water serpent," by the Malays. It does not appear, however, to be exclusively an inhabitant of the waters, though it is generally found near the rivers, or in marshy or humid places. It is a large species, sometimes attaining the length of thirty feet; it kills its prey by crushing, and is the boa constrictor of the eastern world. There are one or two other species of this sub-genus, named by systematic writers, and both described as being much smaller than this one; but it does not appear that, unless in so far as size and strength are concerned, they differ much in their manners; and, from the long life, slow growth, and annual change of skin, and many other circumstances, together with our general ignorance of the habits of the more powerful serpents, it is no very easy matter to say what is a species, and what is not.

**HURRIA.** This sub-genus is altogether doubtful, being probably founded upon an imperfectly formed species of the other; and its specific distinction, which is that of having the scales at the root of the tail single as in the boas, but those toward the point double as in the colubers, is not of much importance.

**DIPSAS.** This name, which is given to an Indian serpent, which is black marked with white rings, is not a very happy one, in as much as dipsas was the Greek name for a fabulous serpent (or one that we may presume to have been fabulous), the bite of which occasioned death by thirst in the person bitten. This species, which is quite harmless, has been confounded with a species of viper of the same country, which is poisonous. The body of this serpent is compressed, not so thick as the head; and the scales along the back are larger than those on the sides, and form a sort of elevated crest.

**COLUBER.** Of this sub-genus there are about 147 species mentioned by the systematic writers on *Ophiology* (or the natural history of serpents considered as a class), and many more are named and probably exist, at the same time it is not impossible that two or three names may, owing to accidental differences of appearance, have been given to the same species. The history of so many species, none of which differ very much in their manners, could hardly be treated in a popular manner, even if the particulars were all well known. But that is far from being the case; so that we must content ourselves with brief notices of a few, both of the European species and of those which are met with in other parts of the world.

*Common Snake* (*Coluber natrix*, *Natrix torquata*), this is the most generally distributed, and on that account the best known, of all the European species.—It is also the only one, or at least the principal one, which is found in Britain, not unfrequently in England, but much more rarely in Scotland. It grows to the length of three or four feet: its back is of a dusky-brown colour, with two stripes formed of a succession of black spots, running the whole of its length; and

these are crossed by irregular spots of the same colour which are very numerous. The belly is dusky with a tinge of blue; and there is a spot of yellow, with a three-cornered one on each side of the neck. These last-mentioned spots compose the collar, from which the species gets the name of *torquata*, or ringed. The head is flattened, and the muzzle rounded; and the head has four rows of large scales, two in the first row, two in the second, three in the third, and four in the fourth. There are seventeen scales in each jaw: the scales on the sides are very small and smooth, without any keel or projection in the middle. There are about 120 plates on the belly, and from fifty to sixty pairs on the under part of the tail. The eggs, which are about eighteen or twenty in number, are deposited in dunghills, hotbeds, and other places where they have the advantage of heat from the fermentation of vegetable or animal matter.

This species is chiefly found in humid places, near the margins of waters, and it takes readily to the water, and is rather an expert swimmer. Its food consists of mice, frogs, insects, and molluscous animals. It is a harmless and even gentle creature, and capable of being tamed, in which state it shows not a little attachment and affection; and gives evidence that it was intended for some useful domestic purpose, for it is a law, and a very beautiful one, in the animal kingdom, that every animal, of whatever race it may be, and whether an inhabitant of the land or the water, which courts the society of man, or even shows no positive reluctance and desire to escape, is in some way or other useful to man, or might be rendered so, if man would study its nature, and attend to the functions which it is capable of performing. But the harmless nature, and the gentle manners, and even the usefulness of this animal, have not been sufficient to protect it from a full share of that very unfounded prejudice which people generally have against the whole of the race. Even the Bard of Avon, who is, generally speaking, as superior as a naturalist as he is as a poet, has helped to perpetuate the animosity with which this gentle creature is attacked. This is the "water" or "fen" snake, which formed one of the ingredients of the "cauldron of diablerie," prepared by the witches, in order to shake the soul of the stern Macbeth, and torment him before his time:

Fillet of a fenny snake,  
In the cauldron boil and bake.

This species of serpent is delicate in its nature, and not found in the colder or more elevated parts of the country. In Scotland, it is very rare, and confined to some of the warmer districts of the south; and although there is a Scotch name for it, there is not a Gaelic one, so that it never can have been common, or even known in the Highlands of Scotland, where here is a name for the poisonous viper. But although it has not been found in the eastern parts of the Highlands, there is some reason to believe that it is by no means rare in Argyleshire, and in some of the more southerly of the Hebrides, where the climate is mild and humid. It is also said to be rather common in many parts of Ayrshire, near the coast, especially about the hills of Dundonald. But as, in Scotland especially, where snakes of any kind are of rare occurrence, and in many places of which, the people will not eat eels because of their snake-like form, every one that can be discovered is instantly killed, and killed with the stigma attached to it that it is a poisonous

viper, or adder, as it is called in that part of the island.

One specimen, differing in its characters from the common species, is mentioned as having been discovered in the south of Scotland, near Dumfries, the plates on the belly of which are stated at 162, and those on the tail eighty. The colours were at the same time paler than those of the common snake, and the dorsal scales without any mesial crest as they have in that species. But the specimen was a very small one, not above five inches in length, and no mention is made of any other instance of its occurrence within the island; so that it is impossible to form any positive conclusion respecting it. The history of British reptiles is a subject which stands in need of far more extensive and more careful investigation than it has hitherto met with; but from the peculiar haunts, the retiring habits, and the long hybernations of most of these animals, the study of them is attended with peculiar difficulties.

*Coluber coronella*. This species is not uncommon in the northern parts of France, and seems to resemble the Dumfries-shire specimen rather more than the Austrian snake does, with which Dr. Fleming, in his account of British animals seems disposed to class it. This one is represented as being of small size, and with all its scales perfectly smooth; the upper part of the body bluish, with two rows of lenticular black spots; the flanks are of a pale reddish colour, clouded in some places with darker; and there are two triangular spots of yellow at the back of the head, which is of an oval form, and covered with very large scales for the size of the animal.

*Coluber viridiflavus*. The green and yellow snake is a very beautiful species, very abundant in the south of France, and especially in the country around Bordeaux. The size varies from two to five feet in length; its head is large, its under part is of a delicate lemon yellow, and the scales on the upper part are alternately intense black and very brilliant green, variously marked in different specimens, but always very rich and beautiful. The tail is longitudinally marked with black and yellow. This species is very expert in climbing trees, and in capturing small birds, and plundering their nests; it is a very delicate creature, and killed by the slightest blow on the back.

*Coluber Austriaca*. Though this species was first discovered in Austria, and named after that country, it is, perhaps, more abundant in the south of France, in Spain, and in some parts of Italy, than it is any where to the northward of the Alps. The upper part has the ground colour of a reddish grey, marked with five small lines behind the eyes, a bar across the back of the head, and two rows of alternating spots along the back, which are brown and blackish. The lower part is iron grey, clouded with darker. Its scales are entirely smooth, and the upper part has a shining lustre. It is but a small species.

*Coluber viperinus*. This species is found in the south of France, in Spain, and in Italy. It is of a brownish-grey colour above, marked with a zig-zag line of spots down the back, which are yellow in the centre, and black at the extremities; there is also a row of very small spots along each side. The under part is mottled with black and grey.

*Coluber tetragonus*. This species, as its name indicates, has the section of the body of a quadrangular form. It is small, rarely attaining a foot in length, and is not so common as many of the other

species, though it is met with in some parts of France. It is a shining serpent, with smooth scales, greenish grey on the upper part, with a row of black dots along the dorsal line, and two parallel ones on the sides. The lower part is yellowish.

*Coluber quadrilineatus*, the four-striped snake. The *Coluber elaphis* of Shaw is the largest of all the European serpents, and is generally understood to be the boa of the ancients. It is yellow on the upper part, marked with four longitudinal lines of brown, or black, and this part of the body has a soft velvety appearance; the under part is black, and glistens with a lustre resembling polished steel. The scales on the back are carinated, but those on the flanks are smooth.

*Coluber flavescens*. This is the Esculapian serpent, *Coluber Esculapii* of Shaw, but not the Esculapian serpent of Linnæus. The species to which he gave that name is a native of America, and of course could not by any possibility be known to the ancient Greeks. This species is very common in Greece, in Italy, and not rare in some parts of France. It is thicker in proportion to its length than any of the European species, and its hiss is much stronger and louder. It is an active animal, and preys equally on the land and in the water, gorging itself while successful, until it is unable to move. Jacquin mentions one that was killed while in the state of semi-dormance, in the stomach of which there were five small birds, a common lizard, and a mullet, which, substituting turtle for lizard, formed three courses worthy of an alderman; and in procuring which we must naturally suppose that this rapacious serpent had laid the air, the earth, and the waters, under contribution within a very short space of time. The colour of the upper part is of an earthen grey, with a longitudinal band of a darker shade on each side; the scales nearest the abdominal plates are white, with black borders on their under edges. The belly is whitish mottled with grey.

*Coluber meridionalis*. This species is found in Provence and the adjoining parts of the South of France. The ground colour above is greyish, with large ash coloured spots on the top of the head behind the eyes, and with four lines of smaller ones along the sides. The spots on the back run into each other two and two; but those on the sides are all separate. The extremity of the transverse plates is black, the middle white, marked with black spots. This is a very small species, and not so common as some of the others.

*Coluber Girondicus* is greyish, with smooth scales, the sides of which form brown bars across; the belly is damasked with yellow and black; the head is compressed, and there is a cross mark on the top of the head. This species has been observed on the banks of the Gironde, where it attains rather more than two feet in length.

*Coluber sanguinolenta*. This species has also been observed on the banks of the Gironde. It bears some resemblance to the Esculapian serpent, but it is smaller, and its colours are differently marked. It is brownish ash, mottled with round spots of reddish brown with black centres, which give it the appearance of being spotted all over with blood, hence its specific name. Its scales are carinated, and its head is large and broad.

The preceding list is considerable, and yet we have no reason to suppose that it includes more than a

fraction of even the European species, of this very extensive genus. In various places of the South, and even in the central parts of the country, colubers are mentioned, differing much both in their forms and their markings, from any of those which we have noticed; but the accounts of them are very vague; and so little is known of the habits of the animals, and the changes of appearance, from age, season, and sex, to which they are subject, and also of the varieties, climatal or otherwise, into which they are apt to run, that we must speak of them with great caution and shall only farther observe of this genus, as European, that it offers a very wide, and far from an uninteresting field of inquiry, to those who are fond of natural history, and who have the means of scrutinising with due attention those wild and semi-aquatic places in which members of the genus are most likely to be found.

In other parts of the world the species are still more numerous than they are in Europe, and some of them attain a larger size. They may all, however, be considered as swallowing serpents, rather than as killing their prey by crushing it to death, though many of them have considerable strength in their folds. They are all perfectly harmless to man, and, generally speaking, of very great service to him, both in the protection of his growing crops, and his magazines of grain. In warm countries the depredations committed by birds, are beyond any extent of which we, of these mild latitudes, have any idea. They come, one hardly knows whence, in flocks which absolutely darken the air, and are quite sufficient to consume the whole crop on a large plantation in the course of an hour or two. In many parts of India, indeed, and in other tropical countries, one of the severest species of field labour which the people are called upon to perform, is that of protecting their crops from the birds. In such countries stages are erected by the sides of all the little cultivated patches, and the youth are kept continually on the alert, hallooing and shouting to scare away the winged plunderers, which are to a very great extent noise proof. In those countries, at least in places where part of the land is under crop, and kept irrigated, so that there is a succession of insects from the supply of water, birds nestle and breed at all seasons; and were it not that there is some means of keeping down their constantly augmenting numbers, they would very speedily obtain the mastery of all nature; for we have evidence in various parts of the animal kingdom, that individual strength is of no avail whatever against combined numbers, be the individuals as weak as they may. We have proof that the antelope, the buffalo, nay even the lion himself in wild nature, may be starved to death by the invasion of the locust; and we sometimes feel in our own country, that the checking of vegetable action for a few days, and the consequent tendency to a saccharine state of the juices, will destroy the crop of our orchards in very brief space. Now when we consider that birds are individually much more voracious than locusts, although the latter ply a very willing tooth, yet we must admit that those means by which the excess of the smaller feathered creatures is kept down in tropical countries, is among the most beneficial to man; and this is a labour which snakes of this genus are incessantly and successfully performing.

COLUMBELLA (Lamarck) VOLUTA, Linnæus). These shells were classed by Linnæus with the genus

*Folula*, from which they are, however, very distinct, having the interior part of the right lip or margin gibbous or thickened, rendering the aperture narrow and waved, and by having also a very small thin elliptical operculum, which latter circumstance, Sowerby observes, allies this genus to that of *Ricinus*. The shells of this genus are short, small, rather thick, often striated transversely, and much varied in colour; in some respects they appear allied to the genus *Mitra*. There are plaits on the columbella, it is more or less notched, and without a canal. The animal is not completely known, it is of the second class *Paracéphalophora*, first order *Siphonobranchiata*, first family *Siphonostomata*. These shells inhabit the seas of hot countries; about eighteen species are enumerated by Lamarck, and one fossil by De France.

COLUMBINE is the *Aquilegia vulgaris* of Linnaeus. It is a native of Britain, but has a good many foreign associates. Their flowers are of very remarkable structure and bright colours, for which they have found their way into every flower garden.

COLUMELLIACEÆ. A natural order of dicotyledonous plants, which has been formed by Mr. Don, and which contains only a few genera as species. It is allied to *Jasmineæ*, and corresponds with that order in the structure and æstivation of its corolla, in its bilocular ovary, and in the structure and dehiscence of its capsule; but it differs in having an adherent ovary, a perigynous disk, an undivided stigma, and an inferior capsule with many-seeded cells. The essential characters, as given by Don, are: calyx turbinate, superior, many toothed; corolla rotate, five to eight partite, with a convolute æstivation; stamens two; anthers linear, one to two celled; ovary inferior, two celled, with an indefinite number of ovules; style simple, declinate; stigma capitate; disk perigynous; fruit, a two celled, many seeded capsule; seeds ascending.

The plants belonging to this order are shrubs, trees, or herbs, with opposite entire leaves, and solitary yellow flowers. They grow in Mexico and Peru. Their properties are as yet unknown. The chief genera of the order are, *Columelia* and *Menodora*.

COLUMNEA (Linnaeus). A genus of undershrubs and climbers, natives of the West Indies. Linnaean class and order *Didynamia Angiospermia*, and natural order *Scrophularinæ*. Generic character: calyx in five parts; corolla tubular, limb erect, and two lipped; upper lip hollow, elongated, and gibbous above the base, with acute reflexed segments on each side; lower lip spreading, and entire; stamens under the upper lip; anthers two celled, and placed close together; fruit a two celled, many seeded, berry. These are pretty flowering plants, and easily propagated by cuttings struck in sand; they are, however, easily lost if over watered or kept in a damp part of the stove.

COLUTEA (Linnaeus). A genus of ornamental shrubs, natives of the south of Europe. They belong to *Diadelphia Decandria*, and natural order *Leguminosæ*. Generic character: calyx of five teeth; standard furnished with two callosities at the base; keel obtuse; stigma on the side and under the apex of a crooked style; pod on a footstalk, inflated, membranaceous. This plant is called bladder-senna in English lists, and is a favourite shrubby genus, as they flower abundantly, and ripen seeds, by which they are propagated.

COLYMBETES (Clairville). An extensive genus of coleopterous insects belonging to the section *Pentamera* subsection *Adephaga*, and family of the water beetles, *Dytiscidæ*. The species are of an intermediate size, and oval form. They frequent ponds, brooks, and other standing as well as running water; they are found throughout the year, but are most abundant in the spring and summer months; they swim with great agility, and may often be seen in hot weather to quit their native element and rise to a considerable height in the air with the assistance of their large wings. There are upwards of thirty British species, including the type *Dytiscus striatus*, Linnaeus; they are generally distinguished by having the tarsi composed of five joints, the four anterior in the males are dilated into an oblong plate, the antennæ are as long as the head and thorax, and the scutellum is distinct.

COMARUM (Linnaeus). A British plant found on most bogs, commonly called marsh-cinquefoil. It belongs to *Icosandria Polygynia*, and to the natural order *Rosaceæ*. This plant was called *Potentilla comarum* by Scopoli, an Italian botanist.

COMBRETACEÆ, the myrobalanæ family. A natural order of dicotyledonous plants, containing eighteen genera, and upwards of one hundred species. It is allied to *Myrtaceæ* and *Onagraræ*, agreeing with those orders in the structure of the embryo and flower. It also bears a strong affinity to *Santalaceæ* and *Elæagnææ* among the monochlamydeous plants.

The essential characters of the order are: Flowers hermaphrodite, rarely polygamous; tube of the calyx adherent to the ovary, limb four or five-lobed, deciduous; petals either wanting, or from four to five in number, arising from the orifice of the calyx and alternate with its lobes; stamens inserted into the top of the tube of the calyx, double in number to its lobes, rarely equal or triple; filaments distinct, awl-shaped; anthers two-celled, bursting longitudinally; ovary one celled, with from two to four ovules, hanging from the extremity of the cell; style one, slender; stigma simple; fruit, a drupe, berry, or nut, one-celled, one-seeded, indehiscent, and often winged; seed pendulous, without albumen; cotyledons leafy.

The plants belonging to this order are trees or shrubs, with alternate or opposite stipuled leaves, and terminal or axillary spikes of flowers. They are found solely in tropical regions, and grow in various parts of India, Africa, and America. They possess in general astringent properties.

The order has been divided into two sections:—1. *Terminaliæ*, corresponding to the *Myrobalanææ* of Jussieu, in which the cotyledons are rolled spirally, calyx five cleft, petals wanting, and stamens ten in number. This division includes the genera *Terminalia*, *Bucida*, *Conocarpus*, &c.—2. *Combretææ*, the true combretum tribe, in which the cotyledons are thick, plaited longitudinally, calyx from four to five cleft, petals from four to five in number, and stamens varying from eight to ten. This section comprehends the genera *Combretum*, *Quisqualis*, &c.

The genus *Terminalia* contains thirty-six known species, many of which are important in a medical and economical point of view. *Terminalia vernix* furnishes a caustic poisonous juice, which is used in China as a varnish. The fruit of *Terminalia bellerica*, is rather larger than a gall-nut when dried, and is administered as a tonic and astringent. *Terminalia chebula* grows in the Malabar woods, and attains the height of eigh-

teen or twenty feet. Its bark and fruit possess powerful astringent properties, and are much used by the Hindoos in arts and manufactures. The flowers are also used in powder, to check bowel complaints. The bark of *Terminalia alata* is met with in the Indian bazaars. It is of a reddish brown colour, has a strong astringent taste, and is used in Ceylon in febrile cases. The juice of the leaves is poured into the ears for the purpose of allaying the pain of earach. The bark also dyes black, and the wood is used in building, and in the formation of boats. The kernel of the fruit of *Terminalia latifolia* is edible, and a decoction of the root of the plant is exhibited in Jamaica in cases of diarrhœa. The kernel of *Terminalia Catappa* has the taste and virtues of the almond. It also yields an oil which is used as an article of food. The tree supplies valuable timber. Its bark and leaves yield a black pigment, with which the Indians dye their teeth, and which is sometimes used in the formation of Indian ink. The fruit of *Terminalia citrina* is about the size of a French plum, and is made into a pickle. *Terminalia angustifolia* furnishes a resinous substance, similar to benzoin.

*Laguncularia racemosa* is one of the plants called mangroves in Brazil, and is used in Rio Janeiro for tanning. The bark of *Bucida Buceras*, known in the Antilles by the name of French oak, is also used for a similar purpose.

The genera *Combretum* and *Quisqualis* furnish some of the most splendid climbing plants of the tropics. When suspended from the trees in these regions, their white, crimson, and yellow flowers have a peculiarly showy and striking appearance.

**COMBRETUM** (Linnæus). A fine genus of ornamental climbers chiefly natives of Africa. Linnæan class and order *Octandria Monogynia*, and natural order *Combretaceæ*. Generic character: calyx funnel formed and four lobed; petals four, inserted in the calyx; so also are the stamens, and opposite the petals; anthers two celled, and burst longitudinally; style pointed; fruit like a nut, containing one seed, and winged; seeds pendent. This beautiful genus is of but late introduction into our collections. In 1818 there were but two species, at present we have at least thirteen. They all thrive well in the compost usually made for stove plants, namely, loam and moor-earth. All the species may be increased by cuttings or layers.

**COMBUSTION, SPONTANEOUS.** There are many facts which lead to prove the existence of this extraordinary natural process. In ordinary cases the combustible substance is set on fire by its temperature being artificially raised by friction, percussion, or the application of some other burning body. Then heat and light are evolved; the body takes fire, and this is what is termed combustion. It arises from the particles of one substance entering into chemical combination with the particles of another; thus pit-coal or fire-wood entering into combination with the oxygen of the atmosphere yield a vast quantity of light and heat; and the more rapid the combination is which takes place, the more vivid is the light, the more intense the heat. Flame, therefore, is the volatilised matter of the combustible body entering rapidly into combination with the oxygen or gas that supports the combustion. In the case of a candle, the tallow or wax is converted into vapour, which enters into combination with the oxygen of the surrounding air,

and becomes heated to whiteness. The flame is a film of this hot white vapour, enclosing within it a quantity of the same vapour, which, when the outer film is consumed, comes in contact with the oxygen, and is in its turn consumed. Hereby the flame is sustained, and as the supply of vapour diminishes as it ascends, the flame tapers to a point. Several substances undergo combustion at a very low temperature. Phosphorus at the common temperature of the air undergoes slow combustion; it emits a white vapour, is luminous in the dark, and is gradually consumed. When combined with a certain quantity of hydrogen it forms a gas, which is so highly inflammable that it bursts into flame the moment it comes into contact with the atmosphere. The illuminating and heating qualities of the coal gas and oil gas are well known; they require, however, to be ignited before combustion takes place. The sources of combustion, or the circumstances which excite the combustible body into a state of combustion, are numerous and sometimes not easily determined. The cause of subterranean fires and volcanoes has been referred to the decomposition of pyrites or the metallic sulphurets which exist below the surface of the earth. Indeed the disengagement of heat is a constant result of chemical action; it is always evolved whenever a substance without change of form passes from a rarer into a denser state; as when a gas becomes a liquid; or a liquid solidifies. In fermentation so considerable a degree of heat is often evolved that visible combustion ensues; hence stacks of hay, turf, flax, hemp, &c., when put up wet, frequently take fire. The light and heat emitted during combustion vary with the nature of the combustible substance; the flame sometimes being white, yellow, blue, orange, or deep red; and the heat often very low, though the substance be ultimately consumed. Several bodies seem to contain light as a constituent, which in escaping renders them luminous, as if surrounded by a lambent flame, varying in colour according to the body whence it arises. The minerals which possess this property are called phosphorescent, as fluor spar, or phosphate of lime. Many animal substances part with their constituent light when they begin to putrefy; thus different kinds of meat and fish, as the haddock, herring, mackerel, when putrefaction commences, appear luminous in the dark. The source of the light and heat given out during combustion is not well understood; many consider the phenomenon entirely electrical. The combustibility of bodies, or their disposition to combine with a greater or less rapidity with oxygen, or any other gas which supports combustion, varies considerably. Many animal and vegetable substances in decomposing give rise to a combination between phosphorus and hydrogen, which produces the gas above referred to, which ignites immediately it comes in contact with the atmosphere. This is the cause of the ignis fatuus or will o' the wisp, which is charged with the sin of betraying weary travellers into bogs and quagmires. The secret, however, is that such places abound with animal and vegetable remains undergoing putrefaction. The mysterious visitants have been detected rising in the form of air-bubbles to the surface of the earth or water, and suddenly taking light. Their flickering motion too may be ascribed to the agitation of the air by which they are surrounded; so that these fairy torches are by the stern exorcism of science divested

of all their supernatural character. Other inflammable gases have been often found existing in nature in a free state, and have been collected in large quantities. In the western part of the State of New York, forty miles from Buffalo, and two from Lake Erie, a village is lighted by its native gas. On removing an old mill, bubbles were seen to rise which were found to be inflammable. A company was then formed, a gasometer constructed, and upwards of a hundred burners were supplied with this gas. In China, near the town of Thae-Lieou-Tsing, springs of inflammable gas have been found. If, according to M. Imbert, a torch be presented to the orifice of a well when the tube full of water is coming up, it inflames and produces a jet of fire from twenty to thirty feet high. These springs are employed for heating and lighting all the salt-works in the neighbourhood. Bamboo pipes carry the gas from the spring to the place where it is intended to be consumed. These tubes are terminated by a tube of pipe-clay to prevent their being burned. A single well heats more than 300 kettles. The fire so obtained is exceedingly brisk, and the cauldrons are rendered useless in a few months. Other bamboos conduct the gas intended for lighting the streets and the different apartments in houses; so that nature has herself supplied this place with a complete establishment of gas-light. It is added that in winter the poor people, in order to warm themselves, dig the sand to the depth of a foot; they then set fire to the gas arising from the hollow so formed, and sitting round it warm themselves as long as they feel inclined. They then fill up the hollow with sand, and the fire goes out. This singular circumstance arises from there being a vast number of coal mines in this district, which contain so much coal gas that it escapes into the strata around them.

When we consider the changes which are constantly taking place in the interior of the earth, it is by no means surprising that inflammable and sometimes poisonous gases should be evolved; it is, however, very remarkable that inflammable gas has sometimes been generated in the bodies of living animals. It is recorded that on opening the body of an ox, which had been some time sick, an explosion took place, and the flame, which rose to the height of more than five feet, scorched severely the butcher and a little girl who stood near him. A case was read by M. Bally to the Royal Academy of Medicine at Paris, of a man who, having been admitted into the Hotel Dieu ill with typhus, died emphysematous, that is, with air effused in the tissue below the skin, and when the skin was punctured a gas escaped, which was set on fire by the flame of a candle. It burned for some time; the flame being blue at its base, white at its summit, and as the body presented no signs of putrefaction, the air having been effused below the skin before death, it was inferred that it must have been generated during life. Another case, which was witnessed by Leduc, is related by Deneux; it is that of a lady from whose body during life a gas proceeded, which took fire and exploded. It is therefore certain that inflammable gases may be developed in the human body during life; and this fact has been adduced in explanation of that curious phenomenon, the spontaneous combustion of the human body. The assertion that the human body may of itself take fire and, with the exception perhaps of a few fragments of bone, be entirely consumed, appears so marvellous that the occurrence may well be at first

doubted; yet on inquiry we shall find that such a mass of evidence exists in proof of its having taken place, that the doubts and suspicions of the most sceptical must be set at rest. In the Transactions of Copenhagen we read that, in 1692, a woman of the lower class who for three years had used spirits to such an extent that she could take no other nourishment, having sat down one night on a straw chair to sleep, was consumed in the night time, so that next morning no part of her was found, excepting the skull and the extreme joints of the fingers. In the Annual Register for 1763, the case is recorded of the Countess Cornelia Bandi, of the town of Cesena, who died in a similar manner. This lady was in her sixty-second year, and well all day until night, when she began to feel a little heavy. After supper she went to bed, and, having talked two or three hours with her maid, fell asleep, upon which the maid servant left the room, closing after her the door. The next morning, on going to call her mistress, she found her corpse in this deplorable condition. Four feet distant from the bed was a heap of ashes, two legs untouched, stockings on, between which lay the head, the brains, half of the back part of the skull and the whole chin burned to ashes, among which were found three fingers blackened. All the rest was ashes which had this quality, that they left in the hand a greasy and offensive moisture. The air of the room had soot floating in it, and from the window a greasy yellowish fluid trickled. Of two candles on the table the tallow was gone, but the cotton left some moisture about the feet of the candlestick. The bed was undamaged, the blankets and sheets being raised on one side, as when a person gets out of bed. This case was published when it took place by Bianchini, the prebendary of Verona; it was also attested by Scipio Maffei, a learned contemporary of Bianchini; and finally confirmed to the Royal Society of London by Paul Rolli. The narration is followed by an inquiry into the cause of the conflagration, the result of which is that it was not from the lamp or a flash of lightning, but that the combustion began spontaneously.

Vicq. d'Azyr, Lair, Kopp, Dupnytren, and Marc, have related a number of other cases, from which, taken collectively, the following inferences have been deduced:—

1. Spontaneous combustion is a calamity almost peculiar to the old and feeble; and those who have suffered have in general been habitual and excessive indulgers in alcoholic liquors.

2. Women seem peculiarly prone to it: thus of seventeen cases collected by Kopp sixteen occurred to females, while the eight cases mentioned by Lair were all females.

3. The flame is of a lambent and flickering nature, of a blue colour, and not readily communicable to other inflammable bodies. Water not only does not extinguish, but frequently gives the flames additional activity.

4. The combustion proceeds with extraordinary rapidity; the decomposition of the entire body being usually effected in a very short space of time.

5. The trunk is generally entirely consumed; but portions of the skull and extremities have been occasionally found left.

6. A strong and peculiar empyreumatic odour is generally exhaled during the combustion, and upon adjacent objects there is found a greasy, moist, and fetid fuliginous deposit.

7. Winter is the season during which spontaneous combustion is most liable to occur, and it seems certain that the combustion in many cases has arisen spontaneously, or without the contact of any ignited body.

We are not aware that any analogous phenomenon has been observed among the inferior animals, or in the vegetable creation. The luminosity of insects—such as the glow-worm, fire-fly, lantern-fly, and of medusæ, which often illumine large tracts of the surface of the sea has however been supposed to arise from the slow combustion of some combination of phosphorus secreted from their fluids. It is not difficult to understand that the human body, when saturated with alcohol, may be the subject of such chemical changes as will render it combustible. There is a large quantity of phosphorus in the bones, and in other parts of the body, and it is easy to conceive that the excess of hydrogen introduced into the system by alcohol, may give rise to such a combination as will evolve the perphosphuretted hydrogen, a gas which, as above explained, takes fire spontaneously; and hence also, water which is composed of oxygen and hydrogen does not extinguish the flame, because it becomes decomposed itself, and its hydrogen uniting with another portion of phosphorus, increases the quantity of the inflammable gas. This theory is by some physiologists thought inadequate to explain all the phenomena that occur, and they therefore have recourse to the calorific power of the electrical fluid. We apprehend, however, that the above explanation is the most satisfactory, and therefore give it a decided preference. The most remarkable fact connected with spontaneous combustion is the rapidity with which the body has, in most cases, been consumed. It is well known that the ancients, in the ceremony of cremation, or the burning of the dead, used vast quantities of fuel; and, to expedite the process, added oil, fat, ointments, perfumes, &c.; yet, notwithstanding, the body was not consumed for a considerable time. Hence Achilles is described by Homer as having attended the burning of the body of Patroclus throughout the whole night. We also know that in the execution of those unhappy persons who were condemned by the inquisition to be burnt to death, a prodigious quantity of combustible materials was required; yet, in most of the instances of spontaneous combustion, the body, without any fuel, and in the space of a very few hours, appears to have been almost entirely reduced to ashes. Were not such cases attested by the most competent and unimpeachable authorities, they might well be doubted; who, however, can prescribe limits to the mysterious operations of nature? It is easy for the ignorant or the indolent to be sceptical, and deny the possibility of every occurrence that has not fallen within the narrow sphere of their own personal observations: the better informed and more philosophical mind, however, will pronounce no such rash judgment, but will pause, and attentively and patiently examine every phenomenon which appears to be well attested.

COMESPERMA (Labillardière). A genus of evergreen shrubs, natives of New Holland, Linnæan class and order, *Monadelphia Octandria*, and natural order *Polygalææ*. Generic character: calyx of five sepals, deciduous; two of the sepals wing formed; corolla of one petal, three-parted; middle segment somewhat cup formed, often imarginate; stamens two bearing anthers; style tubular; capsule wedge shaped,

two celled, and two seeded. Admirable greenhouse plants, which thrive well in light loam and moor-earths but should never be too much soaked with water; to prevent which perfect drainage of the pots is necessary: increased by cuttings.

COMFREY. Is the *Symphytum officinale* of Linnaeus. It is a very common British plant found growing on the banks of wet ditches. Some of the species have tuberous roots, and all are perennials. The rough comfrey, a native of Mount Caucasus, introduced about 1799, has been lately cultivated as an agricultural plant; the leaves being found an agreeable and nutritious green food for cows. The culture is only eligible, when no other agricultural plant can be conveniently raised.

COMMELINA (Linnaeus). A genus of ornamental herbaceous plants, chiefly natives between the tropics, and belonging to the third class of Linnaeus, and made a distinct order by Jussieu, under the title of *Commelineæ*. Generic character:—involucrum double and cupped; calyx of three sepals; corolla of three petals, one or more of the petals often abortive or wanting; stamens three, fertile, with three intervening glands, crossed; stigma simple; seed vessel three celled, three valved; seeds one in each cell. These are pretty blue flowering plants; they may be increased by seeds which ripen frequently, or by dividing the root. Some of them flower in the open air during summer; but if such have tuberous roots, they must be taken up before winter, and kept in dry sand out of the reach of frost.

COMMELINEÆ. The spider-wort family. A natural order of monocotyledonous plants, containing nine or ten genera, and upwards of eighty species. It is allied to *Xyrideæ*, and also to *Restiææ*.

The essential characters of the order are: perianth of six divisions, in a double series, outer tripartite, somewhat resembling a calyx, inner petaloid, with the claws of the petals sometimes cohering at the base; stamens six or fewer, hypogynous, some of them either deformed or abortive; ovary three-celled; style one; stigma one; capsule two or three celled, two or three valved, the valves bearing the dissepiments in the middle; seeds often in pairs, inserted by their whole side on the inner angle of the cell; embryo flat and circular; albumen fleshy.

The plants of this order are herbs, with leaves which are usually sheathing at the base. They inhabit marshy ground in both hemispheres, and are chiefly found in the East and West Indies and Africa. None of them are known in Europe except in cultivation. Many of them are elegant plants, sending forth beautiful clusters of blue, reddish, or white flowers. The first-mentioned colour is the prevailing one of the order.

The chief genera are, *Commelina*, *Callisia*, *Dichorizandra*, *Tradescantia*, *Cartonema*, *Cyanotis*, and *Aneilema*.

The genus *Commelina* was named in honour of two Dutch botanists, called Commelin. It contains nearly thirty species, some of which are showy, while others are mere weeds.

*Callisia repens* is a West India plant, remarkable for its shining leaves, which are edged with purple.

*Tradescantia axillaris*, or axillary spider-wort, is a native of the Malabar coast. A decoction of the plant is considered in that country as a useful remedy in dropsy and in flatulent affections of the bowels. Some of the species of this genus, which is found in

Jamaica, are looked upon as antidotes to the poison of spiders.

**COMOCLADIA** (Linnæus). A genus of large West Indian timber trees, belonging to the third class and first order of Linnæus, and to the natural order *Terebinthaceæ*. Generic character: calyx of three parts; corolla of three elongated petals; stamens short; style none; stigma simple and sitting; drupe of one seed. These trees have been described by Sloane, Swartz, and Jacquin; but they are of too large growth for cultivation in our stoves.

**COMPOSITÆ**. Composite Family. A natural order of dicotyledonous plants, containing between three and four hundred genera, and upwards of four thousand species. It is a very extensive and important order, and is at once recognised by the cohesion of its anthers, and its capitate flowers. On account of the former of these characters, the order has been denominated by some authors, *Synantheræ*. It is allied to *Calyceæ* and *Dipsacæ*, but differs, from these orders in not possessing a pendulous ovulum, and in its anthers not being free.

The following are the characters of the order:—tube of the calyx adnate with the ovary; limb of calyx either wanting, or membranous, or divided into bristles, chaff, hairs, or feathers, called *pappus*; corolla regular and funnel shaped, or irregular and ligulate, sometimes two lipped, generally four or five toothed; stamens four or five, alternate with the teeth of the corolla; anthers cohering in a cylinder; ovary inferior, one celled, with a single erect ovule; one style; stigmas two, either distinct or united; fruit, a small, indehiscent, dry pericarp, crowned with the limb of the calyx or pappus; seed erect, without albumen; embryo straight; radicle directed to the hilum.

The plants belonging to this very natural order are herbs or shrubs, rarely trees, furnished with flowers (called *flosculi*, or florets) which are collected into dense heads on a common broad receptacle, and are surrounded by an involucre. Their leaves are alternate or opposite, without stipules, and usually simple. Among the flowers there exist frequently leafy or chaffy appendages, called *bracteas*. The *Compositæ* are not in general cultivated on account of their beauty, but the order includes several showy and ornamental garden plants.

The order has been variously subdivided by different botanists. In the Linnæan or artificial arrangement, it is included in the class *Syngenesia*, and is divided into sections, according to the sexes of the florets on different parts of the same head. Thus the first section is *Polygamia æqualis*, in which all the florets are hermaphrodite, or furnished with both stamens and pistils. The second section is *Polygamia superflua*, in which the florets of the disk or centre are hermaphrodite or perfect, and those of the ray or margin are furnished with pistils only, but all producing perfect seed. The third section is *Polygamia rustranea*, in which the florets of the disk are perfect, while those of the margin are neuter or destitute of pistils, as well as stamens, and the fourth section is *Polygamia necessaria*, in which the florets of the disk have stamens only, while those of the ray have pistils only, so that both are necessary for the production of perfect seed.

Jussieu, in his natural arrangement, has divided the *Compositæ* into three sections; I. *Cynarocephalææ*, or the artichoke tribe, in which all the florets are

flosculous or tubular; II. *Cichoraceæ*, the succory tribe, in which the florets are all ligulate or strap-shaped; III. *Corymbifereæ*, the corymbiferous tube, in which the florets of the centre are tubular, while those of the circumference are ligulate.

Cassini, Lessing, and Brown, have devoted particular attention to this order, and have divided it into a great number of sections. As these divisions are too minute to be interesting to the general reader, we conceive that it is unnecessary to enter into any details with regard to them. In the observations which we propose to make on the order we shall adopt Jussieu's division, which is the most simple, and the best adapted for a work like the present.

Composite plants are found abundantly in all parts of the world, and are said to constitute almost one-twelfth of the known vegetable productions of our globe. In different countries, the proportion which the *Compositæ* bear to the other phænogamic plants varies considerably. Humboldt states that they constitute one-seventh of the flowering plants of France, one-eighth of those of Germany, a fifteenth of those of Lapland, a sixth of the North-American Flora, and one-half of those of America within the tropics. They form only a sixteenth part of the Flora of New Holland, and the same proportion of the Flora of Melville Island. In their relative increase and decrease, they do not appear to follow any general law of climate. It may be stated generally that the *Cichoraceæ* are chiefly found in cold, and the *Corymbifereæ* in warm regions. The *Compositæ* are herbaceous in the colder quarters of the globe, and become shrubby as we approach the equator.

If we examine attentively the plants belonging to this vast family, we shall find that they are not only naturally grouped together by their structure, but that they also agree remarkably in the medical properties with which they are endowed. They are all more or less tonic and stimulating; they contain a bitter, extractive, milky principle, and a volatile oil which is often solid and concrete, and has a strong resemblance to camphor. Each of the Jussieuan subdivisions of the family present some distinguishing peculiarities in their properties, and we shall therefore notice them separately.

I. **CYNAROCEPHALÆÆ**. The plants in this subdivision of the order possess intensely bitter properties, owing to the presence of much extractive matter, and they act chiefly as tonics. By cultivation, however, this bitterness is much lessened, and the plants in some cases become edible. The volatile oil, characteristic of the family, is not very abundant in this division. Under this division are included the genera, *Cynara*, the artichoke and cardoon, *Carduus*, *Cnicus*, *Onopordum*, *Carthamus*, *Arcetium*, *Carlina*, *Centaurea*, &c.

*Cynara Cardunculus*, common cardoon, was originally a native of the south of Europe and north of Africa, but is now found in various parts of the world. It bears the climate of Britain well, and is said to have been cultivated at Holyrood palace so early as the year 1683. It is an ornamental plant in a shrubbery or large garden. It abounds in the vast plains or pampas of the Cordillera, in South America, and its growth in that part of the world is said to be very rapid. It is stated by a recent traveller in South America, that on the pampas, cardoons shoot up to the height of ten or eleven feet, and come into full flower in the course of a single month. The road

and view become completely obstructed by them, and their prickly stems form a barrier of a most impenetrable nature. The same traveller remarks that, though it would be an unusual misfortune in military history, yet it is really possible that an invading army, unacquainted with that country) might be imprisoned by these plants before it had time to escape from them.

There are several varieties of cardoon which are cultivated as culinary vegetables. The seeds are sown in a deep light soil about the middle of April, and by the end of October the plants have attained their full size, and are ready for blanching. This operation is performed by binding the leaves close together with a wreath of hay or straw, and covering them with earth for a month or six weeks. The stems and mid-ribs of the leaves are stewed, or eaten as a salad. They are also boiled in soups. The florets of the cardoon are used in Buenos Ayres and in France instead of rennet, for coagulating milk.

*Cynara scolymus*, the common artichoke, has been considered by some as merely a variety of the cardoon, depending on the cultivation. This opinion requires confirmation, and as yet we have not sufficient data to enable us to come to a satisfactory conclusion. The artichoke differs from the cardoon in its broad spineless leaves, its humble growth, and its large fleshy heads. The plant comes originally from the south of Europe, and was cultivated in England so early as the year 1580. It is capable of sustaining great and long-continued drought. In the hot season of 1825, it was almost the only vegetable to be got in the neighbourhood of Paris for three or four weeks in the months of July and August. Once in the seventeenth century, and again about 1739, most of the artichokes in England were destroyed by frost, and recourse was had to France for a new supply. There are several varieties of artichoke in cultivation, the chief of which are the green or French. The globe and dwarf globe artichokes are propagated by suckers, in the months of March and April. They require a light well-manured soil, and are planted in rows four feet distant, and two feet apart in the rows. They produce a few heads the first season, and a full crop the next; and, if well manured, they will last for five or six years. In winter, the plants are covered with dung about a foot thick, which is removed in March and April when the ground is dressed. The artichoke, in its wild state, is more downy and spinous than when cultivated in the kitchen garden; the heads also are much smaller.

The heads of the artichoke are gathered in the unripe state before the flower expands, and are boiled in salt and water until all the parts are soft which are capable of becoming so. The scales are then taken off one by one, and their lower part being dipped in a mixture of butter and pepper, all the fleshy part is sucked off. Very little is obtained in the way of solid food, the butter forming the chief part of the dish. After the scales are taken off, there remains the receptacle or bottom, with a mass of unexpanded florets and bristles, called the *choke*. The latter being removed, there remains the proper receptacle or *cul* which is the most valuable part of the artichoke. Many people are very fond of artichokes. In France and Italy they are much more used than in this country, and they are often eaten in those countries in a raw state.

Artichokes contain little nourishment, but they are easily digested, and hence are sometimes useful for

convalescents. They possess diuretic and diaphoretic properties. The root is bitter, and is considered by the Arabians as laxative, while the gum which it furnishes is classed by them among the emetics. The receptacles of the artichoke may be preserved during the winter, by being blanched in hot water, and carefully dried.

The genera *Cnicus* and *Carduus* include most of the thistle tribe. These two genera are distinguished from each other by the pappus being feathery in the one, and only rough in the other. Thistles are propagated with amazing rapidity, on account of the down attached to their seeds, by means of which they are easily carried by the winds in all directions. They are a very troublesome set of plants, and prove a great annoyance to the farmer. Ever since the time that the Almighty pronounced this sentence on the earth, "Thorns also and thistles shall it bring forth to thee," these weeds have continued to infest the ground, and man has been forced to eat bread in the sweat of his brow. The *Cnicus arvensis*, or creeping thistle, is one of the most difficult to extirpate, in consequence of the numerous deep roots which it puts forth. These noxious weeds, however, although at first sight they might appear to be of no use, have important purposes in the economy of nature, affording by their seeds and leaves nourishment to numerous tribes of birds and insects with which the earth is peopled. Some of the thistle tribe are also turned by man to useful account: the footstalks of their leaves, and their receptacles, being used by him as food. The flowers of several of the species are used in Europe for curdling milk.

The handsomest native species of thistle are, *Carduus nutans*, *Cnicus eriophorum*, and *heterophyllus*. The first of these is said to smell powerfully of musk in warm weather, more especially in the evening, and hence it has been called musk thistle. *Cnicus eriophorum*, woolly-headed thistle, is so named on account of the large quantity of woolly matter which is interwoven with the scales of the involucre. *Carduus Marianus* has been denominated milk thistle, on account of the milky veins on its leaves. The root and leaves are very bitter, and the expressed juice was formerly used in dropsy, jaundice, chronic rheumatism, and intermittent fever. *Onopordum acanthium*, common cotton thistle, although not belonging to the true thistle tribe, and but rarely found in Scotland, is still commonly cultivated as the true Scotch thistle. Its seeds are much eaten by birds, and are not so liable to be blown about as those of the other thistles already noticed.

*Carthamus tinctorius*, safflower, is a native of Egypt and eastern countries, and is cultivated in many parts of Europe and the Levant, on account of its flowers, which are dried and exported in large quantities, in order to furnish a deep yellow dye, like saffron. The flowers furnish two colouring principles very important in dyeing; one soluble in alkalis, presenting various shades of red, and another soluble in water, of a yellow colour. The first is employed particularly by the Chinese, to give different red tints to silk, and bears the name of *Carthamite*. When mixed with finely powdered tale, it is used by the Parisian ladies as a cosmetic rouge, under the name of vegetable rouge, or lake of *Carthamus*. The plant was introduced into England in the year 1551, and in 1683, twenty-five acres of ground in Gloucestershire were sown with its seeds. In Spain it is grown in gardens for the pur-

pose of colouring soups, and the Jews in Poland employ it much in their viands. The seeds are purgative, and have been recommended in dropsy. Though bitter, they are eaten by birds, especially by parrots, and hence they are sometimes called parrot grains.

*Carthamus lanatus* is used by the women in the south of France and Spain for distaffs, and hence it is denominated distaff thistle.

*Arctium lappa*, common burdock, and *Arctium Bardana*, which seems to be merely a variety with a downy calyx, are well known on account of the hooked scales of their involucre, by means of which the heads fasten themselves most pertinaciously to clothes and the coats of animals. The seeds are oily and bitter, and the whole plant possesses diuretic, diaphoretic and aperient qualities. The root contains carbonate and nitrate of potass; and a decoction of it has been used as a substitute for sarsaparilla, and administered in cutaneous and rheumatic affections. The juice of the leaves mixed with oil forms a liniment which has been used in dressing wounds and ulcers.

*Centaurea benedicta*, blessed thistle, a native of the Grecian islands, is accounted a stomachic, and its seeds are used to produce perspiration. An extract from the plant has been recommended in the catarrh of children. *Centaurea calcitrapa*, common star-thistle, possesses febrifuge virtues. Its roots were formerly considered useful in calculous complaints, and its leaves and flowers were prescribed in ague. *Centaurea cyanus*, corn blue-bottle, has been sometimes employed medicinally. The juice of its flowers is used as a kind of ink, and stains linen of a blue colour.

*Carlina acanthifolia* is a wholesome article of diet. *Carlina acaulis* has black woody roots, an inch in thickness, the upper part of which, as well as the receptacle of the flowers, may be eaten. The flowers of *Echinops strigosus* are used in Spain for tinder.

II. CICHORACEÆ. Most of the plants of this tribe yield a milky juice, which is bitter, astringent, and slightly narcotic. To this juice they owe their medical properties; and, when it exists in great quantity, the plants may be looked upon with some degree of suspicion. Many of the *Cichoraceæ* are employed as articles of food, either in a young state, before the bitter narcotic juice is fully formed, or in a more advanced state, after being blanched. By cultivation a great change is often effected in their qualities.

The chief genera included in this sub-division of composite plants are, *Cichorium*, the succory and endive; *Lactuca*, the Lettuce; *Sonchus*, *Leontodon*, *Scorzenera*, *Tragopogon*, *Hieracium*, *Apargia*, *Lapsana*, &c.

*Cichorium intybus*, common wild succory, is met with chiefly on gravelly and chalky soil, in several parts of Britain, and is very abundant on the continent. It bears numerous large bright but pale blue flowers, which close during the night, but expand on the first approach of morn. The plant was eaten by the Romans, and is still used as an article of food in France. The seeds are sown in July, and the plants are allowed to grow six inches apart. In winter the roots are taken up and packed in a warm cellar among earth, the upper portion being the only part exposed. In this situation, young leaves are quickly produced, in a blanched state, fit for being used as a salad. The leaves and root are very bitter in a wild state, less so when cultivated. The juice of the fresh leaves acts as a tonic, and a stomachic syrup is prepared from them. The root, when dried and roasted, has an agreeable bitter flavor, and is used on the continent as a

substitute for coffee. At one time when the latter article bore a high price in the market, succory was much used in France, and it is still employed in that country, although it certainly wants the fine aroma of the Arabian grain. The herb in a luxuriant cultivated state, is an excellent early fodder for cattle.

*Cichorium endivia*, common endive, is a native of Japan and China, and is cultivated in gardens for the purpose of furnishing the salad which bears its name.

The genus *Lactuca*, lettuce, furnishes several species, three of which, *Lactuca virosa*, strong-scented lettuce; *scariola*, prickly lettuce; and *saligna*, least lettuce, are natives of Britain. *Lactuca virosa*, wild or strong-scented lettuce, yields a milky juice, having a disagreeable and well-marked narcotic odour. In its medical properties and effects, it bears a considerable resemblance to many of the *Solanaceæ*. An extract is prepared from it, which is used as a substitute for opium. A large quantity of this plant was cultivated about a year ago in the neighbourhood of Edinburgh, by a celebrated druggist of that town, and the concrete juice procured from it was sold extensively in the London market.

*Lactuca sativa*, common lettuce, is another species of the genus. This plant has been cultivated in gardens, almost from time immemorial, and its native country is not known. There are several varieties of cultivated lettuce. The leaves of all have a fresh, watery, and somewhat bitter flavour, and are used much as a salad. Lettuce thrives well both in temperate and warm regions.

The inspissated juice of this, as well as the former species, is called *lactucarium*, and was first introduced into notice by Dr. Duncan of Edinburgh. This substance is called by the French physicians *thridace*, from the Greek word for lettuce. Although *lactucarium* is procured from both species of *lactuca*, still the *lactuca virosa* yields it in greatest quantity. The juice, which exists chiefly in the vessels immediately under the cuticle, ought to be collected at the time when the plant is in flower, and the mode of procedure is as follows:—Transverse incisions are made successively in the stems of the plants, and the white or milky juice, which exudes copiously, is scraped off. It is then put into glass or porcelain vessels, and allowed to concretize by exposure to the air. It thus assumes a brown colour. The *thridace* of the French is procured by expressing the juice, and consequently it is not so pure as the British *lactucarium*.

*Lactucarium* varies much in purity, according to the season, as well as the mode of its preparation. It often contains a great quantity of caoutchouc, which, of course, interferes much with its properties. It has much of the taste and odour of opium, and exerts a soothing anodyne effect upon the system. Duncan, Young, Scudamore, Bidant, and Francis, have used it extensively in the cure of diseases. It may be administered in most cases where the use of opium is indicated in doses of five, ten, or even twenty grains. It would seem not to produce the prejudicial effects which often attend the use of opium. The narcotic principle of *lactucarium* has not yet been procured in a separate state. No morphia could be obtained from it. *Lactucarium* has also been used as a diuretic in cases of dropsy and water in the chest.

The soporific effects of lettuce have been long known. Galen is said to have used it much in the decline of his life, on account of constant wakefulness.

The seeds of the lettuce also possess narcotic qualities, and the leaves when boiled in water have been used as soothing poultices.

*Lactuca quercina*, *Palmata* and *Intybacea* are cultivated by the French as salads.

*Sonchus oleraceus*, common sow-thistle, possesses diuretic and laxative properties. The young tender leaves of this plant, as well as those of *Sonchus arvensis* and *palustris*, are eaten as greens in some countries. In Rome and Florence, *Sonchus tencrimus* is used as a salad. Swine are said to be fond of these plants, and hence the English name *sow-thistle*, which has been applied to them. *Sonchus Alpinus* bears numerous large blue flowers, and is the rarest British species. It is found only in one or two stations in the Grampian range.

*Leontodon taraxacum* receives the names of *Dent de Lion*, *Dandelion*, lion's tooth, from the deep tooth-like divisions of its leaves. The plant has a considerable degree of bitterness, but when blanched like endive, it may be used as a salad. The tender young leaves, in consequence of being less bitter, are often used for this purpose. The root resembles a carrot, and yields a bitter milky juice, which loses its bitterness by drying. When roasted, it is used by the common people in some parts of Germany as a substitute for coffee. Medically dandelion acts as a tonic and diuretic. The expressed juice of the leaves is said to be useful in chronic cutaneous diseases, and in abdominal obstructions. In jaundice and diseases of the liver it has also been frequently employed. The plant is a troublesome weed, and is extirpated with great difficulty.

The genus *Scorzonera* derives its name from the Catalan word for a viper, the plant being considered in Spain to be a remedy for the bite of that reptile. The root of *Scorzonera Hispanica*, garden or Spanish viper's-grass, is carrot-shaped, about the thickness of a finger, and bears some resemblance to the body of a viper. When deprived of its outer skin, and boiled or stewed, it forms an agreeable article of food. The plant is said to possess diuretic, stimulant, and sudorific qualities. The genus *Tragopogon*, goat's-beard, furnishes several species, three of which are natives of Britain. *Tragopogon pratensis*, common goat's-beard, bears yellow flowers, which close every day before noon. *Tragopogon porrifolius*, salsify or purple goat's-beard, has a long, fleshy, white root, possessing a mild sweetish flavour, which was formerly used in Britain as an article of food. The plant bears large purple flowers, which close before noon, or in rainy weather.

Several of the plants belonging to this section of the *Compositæ*, act as horological flowers, their petals expanding and shutting regularly at particular hours in the day. We have examples in the common goat's-beard, the common succory, the common sow-thistle, dandelion, and various species of *Hieracium* or hawk-weed. These plants act thus as silent monitors, warning us of time's rapid flight. To use the poet's language—

"In every copse and sheltered dell,  
Unveiled to the observant eye,  
Are faithful monitors who tell  
How pass the hours and seasons by.

"The green-robed children of the spring  
Will mark the periods as they pass,  
Mingle with leaves Time's feathered wing,  
And bind with flowers his silent glass.

"See *Hieracium's* various tribe  
Of plummy seed and radiate flowers,  
The course of time their blooms describe,  
And wake or sleep appointed hours.

"Broad o'er its imbricated cup  
The *Goatshead* spreads its golden rays,  
But shuts its cautious petals up,  
Retreating from the noontide blaze.

"On upland shores, the shepherd marks  
The hour when, as the dial true,  
*Cichorium* to the towering lark  
Lifts her soft eyes serenely blue.

"Thus in each flower and simple bell,  
That in our path betrodden lie,  
Are sweet remembrancers who tell  
How fast their winged moments fly."

III. CORYMBIFERÆ. The plants belonging to this subdivision are in general very active in their qualities, and supply various therapeutical agents. Like the other *Compositæ*, they contain a bitter principle; and in the composition of many of them we find large quantities of volatile oil and camphor. To the existence of these substances we trace the powerful aromatic odour which many of them emit, as well as their stimulating medical properties. The principal genera included in this section are, *Anthemis*, chamomile; *Achillea*, *Helianthus*, *Absinthium*; *Artemisia*, wormwood; *Tanacetum*, tansy; *Balsamita*, *Matricaria*; *Calendula*, marigold; *Arnica*, *Inula*, *Tussilago*, *Gnaphalium*, *Senecio*, *Dahlia*, *Bellis*, &c.

*Anthemis nobilis*, common chamomile, is a perennial plant, found native in the southern counties of Britain. It is cultivated in gardens for the sake of its flowers, which are easily rendered double, and are used medicinally. The plant diffuses a highly aromatic and agreeable odour owing to the presence of a blue volatile oil, which may be procured by distillation. Besides this oil it contains camphor, gum, resin, and a small quantity of tannin. An infusion of the flowers is used as a tonic, stimulating, diaphoretic drink. It is also employed as a febrifuge, and has been administered with success in slight agues. It produces vomiting, and is useful in aiding the effect of other emetics. Chamomile is used as a remedy in spasmodic diseases, such as hysteria and colic. The flowers are applied externally as a discutient and emollient.

*Anthemis cotula*, stinking chamomile, is another British species, which is found in waste places, in corn-fields, and by way-sides. The whole plant emits a very disagreeable fetid smell, and is said to blister the hands of those who gather it. On examination with the microscope, it is found to be covered with small glands, which probably contain an acrid fluid. The plant is a stimulant, antispasmodic, and is used in nervous diseases.

*Anthemis pyrethrum*, pellitory of Spain, is a native of Spain, Barbary, and other warm countries, but bears the ordinary winters of this country well. The root, when pulled up and applied to the hand, communicates a peculiarly cold sensation. When chewed it produces a copious secretion of saliva, and a pricking sensation in the tongue. It is used in toothach, headach, and palsy of the tongue. It contains volatile oil, gum, and muriate of lime.

*Anthemis tinctoria*, ox-eye chamomile, supplies a beautiful yellow colour, and is used in dyeing.

*Achillea millefolium*, common yarrow or milfoil, is found abundantly in pastures and by way-sides in this country. From its astringency it is used in the

Highlands for the purpose of healing wounds. The root has been proposed as a substitute for snake-root.

*Achillea ptarmica*, sneezewort yarrow, when dried and powdered, is employed as an errhine. The root, when chewed, produces salivation.

*Achillea nana*, and several other species, are used by the inhabitants of the Alps to give an aromatic flavour to vinegar.

*Helianthus annuus*, common sunflower, is a well known border annual, which receives its name from the popular supposition that its large heads of flowers follow the sun in its course. The plant is common in gardens, and was originally brought from Peru. The whole plant, but especially the flower, gives out a thin resin resembling Venice turpentine. The seeds, when roasted, are used as a substitute for coffee, and an edible oil is procured from them.

*Helianthus tuberosus*, Jerusalem artichoke, is a native of Brazil, but has been naturalised in most countries of Europe, and is cultivated on account of its use in rural and domestic economy. The root of the plant consists of oblong tubers, which are used as a substitute for potatoes, and form a wholesome and agreeable article of diet. The roots are very productive. Between seventy and eighty tons of tubers are said to have been obtained in one season from a single acre of ground. When boiled, the roots have a sweet taste similar to the artichoke. The plant may be reared on very poor soil with advantage, but its roots are not so much employed as the potato, on account of the latter containing more nutritive matter in its composition. Chemical analysis has shown that a peculiar principle, similar to that which is found in the dahlia, exists in the root of the Jerusalem artichoke. The roots when subjected to fermentation yield a spirituous liquor.

*Absinthium officinale* or *Artemisia absinthium*, common wormwood, is an aromatic bitter plant, common in Great Britain. It contains a large quantity of a green volatile oil. The plant possesses tonic and stimulating qualities, and is used to increase the action of the stomach, as well as for the cure of intermittent fever. It is frequently given to expel worms. It is administered in the form of powder, in doses of one or two scruples, also in infusion, and as a wine and a tincture. The green liquor called, in France, *eau d'absinthe*, and employed by gourmands to increase their appetite, is prepared from the plant by the addition of alcohol and subsequent distillation.

*Artemisia* is another genus of this order. It differs from *Absinthium* in the want of hairs on the receptacle. It includes several species, four of which are natives of Britain.

*Artemisia vulgaris*, mugwort, is not so bitter and aromatic as *Absinthium*, and has a less powerful action on the human frame. It is a stimulating tonic, and exerts a peculiar action on the uterine system. Its root has been recommended in epilepsy. In some parts of Sweden the plant is used in place of hops to increase the inebriating quality of malt liquors.

*Artemisia dracuncululus* is a native of Siberia, but is commonly cultivated in gardens. The leaves have an aromatic fragrant taste, and are used as an ingredient in pickles and salads. An infusion of the plant in vinegar forms a good fish-sauce.

*Artemisia Santonica* or *Judaica*, wormseed, is found in Arabia, Judea, and the countries in the north of Africa. The heads, seeds, and upper twigs of this plant, mixed with those of another species found in

Persia, and called *Artemisia contra*, are known in commerce by the name of *Semen contra* or *Sementina*. There are two varieties of *Semen contra*, one coming from the Levant, and the other from Barbary. The first is the best, and held in greatest repute. It is chiefly administered as a vermifuge in doses of twenty or thirty grains mixed with calomel or rhubarb.

*Artemisia abrotanum*, southernwood, is a perennial shrub, a native of the south of Europe, but common in gardens. It has a strong smell, and yields a fine green tincture. It is administered as an anthelmintic and sudorific, and is also employed externally as a fomentation. In the form of lotion or ointment it is applied to cutaneous eruptions, and is said to prevent the hair from falling off.

*Artemisia Chinenus*, mugwort of China, furnishes the moxa used by the Chinese as a cautery. This is a soft woolly substance, prepared from the young leaves of the plant by beating them, when thoroughly dried, and rubbing them in the hands till the fine fibres only are left. A little cone of this substance is laid on a diseased part, previously moistened, and is then set on fire at the top. It thus burns slowly down, producing a dark spot on the skin, which ultimately sloughs and produces an eschar. This mode of treatment is much used in eastern countries. The moxa used in this country and in France is generally made of cotton or linen rag, dipped in saltpetre, and rolled up tightly in a circular form. It is frequently employed as a powerful means of counter-irritation in diseased joints, &c.

*Tanacetum vulgare*, common tansy, is a well-known native plant. It has a strong, disagreeable, aromatic odour, and a bitter pungent taste. Its stimulating qualities are owing to the presence of a great quantity of essential oil. It is administered in the form of powder and infusion, as a remedy for worms and gout; and it is praised as an anti-spasmodic by some authors. The young leaves are sometimes employed to colour and flavour puddings.

*Balsamita suaveolens* is often cultivated in gardens. It has a strong odour, and possesses stimulating anti-spasmodic qualities. When steeped in oil, it is looked upon as a good application to wounds and bruises.

*Balsamita vulgaris*, costmary, from being put into ale, sometimes receives the name of *Cost-ale*.

*Matricaria chamomilla*, wild chamomile, has properties similar to those of the true chamomile. It is, however, much less powerful, and is now seldom used.

*Pyrethrum Parthenium*, common feverfew, has stimulating aromatic properties, and is employed in various fluxes.

*Calendula officinalis*, common marigold, is a well-known showy ornament of gardens, even that of the humblest cottager. It was introduced into this country, from the south of Europe, in the year 1573. Linnaeus says, that its flowers expand from nine in the morning till three in the afternoon—

"The Marigold that goes to bed with the sun,  
And with him rises weeping."

Its flowers are used in some parts of England to give colour and flavour to soups, and a distilled water and a kind of vinegar have been prepared from them.

*Arnica montana*, German leopard's bane, is found on the Alps and Pyrenees, as well as in various parts of Germany, Sweden, and Lapland, and was first cultivated in Britain in 1759. The flowers are of a

yellow colour, and contain an odoriferous resin, bitter nauseating matter, yellow colouring matter, gallic acid, gum, albumen, and some salts. In its recent state the plants excites sneezing in those who smell it. The flowers and root are used medicinally.

The plant has a bitter, acrid, and nauseous taste, and possesses stimulating properties. It produces a peculiar effect on the brain and nervous system, giving rise to headach, spasmodic motions of the limbs, and difficulty of breathing. It has been used in intermittent fever and dysentery; and of late has been prescribed in palsy, blindness, and various nervous affections. It is administered in the form either of infusion or powder. The dried leaves are sometimes used as a sternutatory in place of tobacco. When given in too large doses, arnica excites a feeling of anxiety, shooting and burning pains, vomiting, giddiness, and insensibility. In these alarming symptoms, vinegar is said to be the best remedy.

*Inula Helenium*, elecampane, is one of the largest herbaceous plants of Britain. Its root contains albumen, a volatile concrete oil like camphor, and a peculiar starch-like matter called *inulin*, which does not gelatinise on the addition of hot water, but remains in the form of powder. Elecampane is tonic, stimulant, and diuretic. It is sometimes prescribed in the form of infusion, powder, or wine, at the conclusion of catarrhal affections.

The young branches of *Inula crithmifolia* are sold in London as a substitute for samphire. *Pulicaria dysenterica*, common flea-bane, a plant found in marshy places in Britain, is sometimes recommended in dysenteric affections. *Spilanthes oleracea* has a hot penetrating taste, and is one of the most powerful anti-scorbutics which we possess.

*Santolina chamaecyparissus*, cypress-leaved lavender cotton, has properties similar to tansy, while *Solidago virgaurea*, common golden rod, is diuretic, aperient, and vulnerary.

*Eupatorium perfoliatum*, known in North America under the name of *Boneset*, possesses important tonic and diaphoretic properties.

*Eupatorium Ayapana* is celebrated for its power of curing the bites of serpents; and *Mikania Guaco* is used in Spanish America for a similar purpose.

The various species of *Guaphalium* and *Xeranthemum* constitute the plants commonly known by the name of *Everlasting*. *Coreopsis tinctoria* is a very handsome border annual, and *Chrysanthemum Sinense* is one of the handsomest autumnal flowers. *Asters*, Christmas daisies, or star-worts, although not of much beauty, are prized on account of their flowering late in the season. China asters are familiar to all as annuals.

*Bellis perennis*, common daisy, so abundant in every pasture, is too often despised on account of the frequency of its occurrence. How different are the feelings with which this plant is contemplated by natives of Britain, when resident in countries where the daisy is not indigenous. How many pleasing and delightful associations does it in such circumstances awaken, when, perchance, it springs up along with other exotics! Among some English earth, in which seeds had been conveyed to Dr. Carey in India, there sprang up to his great delight the *daisy*; and this he perpetuated as an annual, raised by seed preserved from season to season. The feelings excited in Dr. Carey's mind by this incident are beautifully depicted by Montgomery in his "Daisy in India."

Thrice welcome little English flower!  
My mother-country's white and red,  
In rose or lily, till this hour,  
Never to me such beauty spread;  
Transplanted from thine island bed,  
A treasure in a grain of earth,  
Strange as a spirit from the dead,  
Thine embryo sprang to birth.

Thrice welcome little English flower!  
Of early scenes below'd by me,  
While happy in my father's bower,  
Thou shalt the blithe memorial be;  
The fairy sports of infancy,  
Youth's golden age and manhood's prime,  
Home, country, kindred, friends, with thee,  
I find in this far clime.

Thrice welcome little English flower!  
To me the pledge of hope unseen;  
When sorrow would my soul o'erpower,  
In joys that were, or might have been,  
I'd call to mind how fresh and green  
I saw thee waking from the dust;  
Then turn to heaven, with brow serene,  
And place in God my trust.

*Tussilago farfara*, coltsfoot, is common in moist clayey soils in this country. The flowers appear early in spring before the leaves. The plant is mucilaginous, bitter, and astringent, and in the form of infusion is used in chronic catarrhs, accompanied with cough and expectoration. The leaves are sometimes smoked like tobacco, for the relief of asthmatic complaints. The down, or cottony web covering the leaves, is used as tinder, and as a styptic for slight wounds.

The flowers of *Petasites vulgaris*, common butterbur, are of a pale flesh colour, and grow in the form of a thyrsus. In consequence of the plant flowering early, it is placed by the Swedes near their bee-hives.

The species belonging to the genus *Senecio*, or groundsel, are found in every part of the world, more especially in South Africa. Humboldt has observed that they are very numerous in the upper regions of the Andes, just below the limits of eternal snow. The flower buds and young tops of the leaves serve as food for birds, and canaries are particularly fond of them.

The genus *Dahlia* is named after Andr  Dahl, a Swedish botanist, and a pupil of Linn us. *Dahlia superflua*, is a native of Mexico. Till the peace of 1814, this plant was much more cultivated in France than in Britain. It has now become a very fashionable plant in this country, and is considered one of the finest ornaments of our gardens. The flowers are showy, and continue to expand late in the season. There are numerous single and double varieties of the dahlia; the former being procured from seeds, the latter from cuttings, graftings, and divisions of the roots. The roots are taken up in winter and kept dry, and are again planted out in April. Benzoic acid is said to exist in the dahlia.

From the remarks which have been made on this comprehensive order, it will be seen that it contains plants possessing valuable medical properties, and that it also furnishes many of those vegetables which are used for culinary purposes. Whether we regard the vast number of species which this family contains, their wide distribution over the globe, or the highly important qualities with which they are endowed, we must consider it as occupying a distinguished place among the various tribes of vegetables which diversify the surface of the earth.

COMPTONIA (Banks). A North American deciduous shrub, named in honour of, and to perpetuate the memory of Henry Compton, bishop of London, an indefatigable collector of useful plants in

the early part of the last century. Linnæan class and order *Monæcia Triandria*, and natural order *Amentaceæ*. Generic character:—male catkin cylindrical, loosely imbricated; scales one-flowered; perianth of two leaves; corolla none; filaments three, forked; anthers six, two valved. Female catkin ovate, thickly imbricated; scales one-flowered; perianth of six leaves; styles two, like hairs; nut one-seeded. The leaves of this shrub are somewhat like those of fern, it thrives on light sandy loam and moor-earth, and is increased by layers.

**CONANTHERA** (Ruiz and Pavon). A genus of Chilean bulbs, belonging to *Herandria Monogynia*, and to the natural order *Asphodeleæ*. Though not so splendid as others of the same class and character, they are, however, interesting, and well worthy cultivation. Mr. Sweet observes of this genus—"We believe that this and some other nearly related ones, would succeed better if out in a frame, on a warm border, and be covered with a mat or other covering in severe weather, than they do in pots."

**CONCHACEA**. The eighth family of the third order *Lamellibranchiata*; third class, *Acephalophora*, of De Blainville's system. It includes the genera *Cardium*, *Donax*, *Tellina*, *Lucina*, *Cyclas*, *Cyprina*, *Macra*, *Erycina*, *Crassatella*, *Venus*, *Venerupis*, *Coralliophaga*, *Clotho*, *Corbula*, *Sphæna*, and *Usgulina*. The shells of this family are all of them bivalve, and constitute a numerous portion of the most beautiful molluscs. The general characteristics are:—the shell nearly always regular; perfectly closing; equivalve, the summit recurved forward; the hinge, dorsal and complete, that is, with teeth and ligament, either exterior or interior, short and swollen; two distinct muscular impressions.

The mantle of the animal is closed in front, above, and backwards, where it is prolonged by two tubes more or less long, extensible, either united or separate, the abdomen constantly furnished with a foot, varying somewhat in form, which is its only organ of locomotion. All the animals of this family live concealed in the sand or mud, at a greater or lesser depth, but they have the faculty, and sometimes quit that situation; this is effected by contracting the foot, which then acts as a spring, and they are propelled forward. Their natural position is with the valves downwards when concealed in the sand, and they then move forward by slow degrees, in which operation the foot acts as a lever to assist their march. Under the respective names of the genera composing this family, the particular description of each species will be found.

**CONCHOLEPAS** (Lamarck); **PATELLA LEPAS** (Linneus). By many naturalists, this singular shell has been considered a *Patella*, with which it was classed by Linneus, from which it is most widely different, by many characteristics, and particularly by two distinctions, that of having a spire and being an operculated shell. This error may, in some degree, be accounted for, by supposing that great man had only examined an injured specimen of the shell, in which the extremely small spire had been worn off; that being frequently the case, the shell being generally much worn; and, as he paid little or no attention to the animals of shells, the operculum, no doubt, was never seen by him. Brugnière, observing the spire, classed this shell with the *Buccina*, a far more natural association: this he did also on account of the slight notch at the base; but Sowerby has yet more properly considered it allied to the *Purpura*. From these consider-

able doubts exist in our mind of the propriety of separating them. Lamarck classed this genus immediately following that of *Monoceros*, from having two teeth at the base of the right side instead of one; but what he termed teeth, are no more than the continuation of two external thickened ribs, which, being flattened and broad, in no respect resemble the tooth of the *Monoceros*, which is a distinct sharp-pointed, round, slightly convex point, and very differently situated with regard to its position on the shell. Lamarck's description of the shell is:—shell oval, inflated, half spiral, the summit inclined obliquely on the left side; columella flat, aperture very ample, oblique, longitudinal, and with a slight notch at the base; two teeth at the lower part of the right margin. To this we must add some other striking and constant characters. The small spire is formed of three whorls, the apex pointed; it is nearly concealed by the very widely expanded aperture, the left side of which is greatly reflected, and forms a sharp angle above it; the right lip crenated at the base; the exterior presents transverse grooves, or slightly formed ribs diverging from the apex to the margin, and imbricated with small scales and a horny operculum very closely resembling that of the *Buccinum* or *Purpura*. We conclude the animal to be altogether unknown, not having met with any description of it. Of this singular genus the only species known is from the coast of Peru, and is here figured. In beauty, this shell has little

Concholepas Peruvianus,

to recommend it, but, to the conchologist, it presents much interest, as it is one of the well-defined instances of the links of connexion existing throughout the classes and genera of shells; it illustrates that system of gradation which, sooner or later, will complete one general chain, and explain many phenomena, well grounded in theory, but badly accounted for by examples. In the system of De Blainville, this genus is placed in the second class *Paracephalophora*; first order *Siphonobranchiata*; second family *Entomostomata*—if immediately follows the genus *Purpura*, and precedes the genus *Stronbus*, but it is not unlikely that it will ultimately form a division of the first, from which we consider its separation as only temporary.

**CONCHOLOGY**. Under this title, or that of **TESTACEOLOGY**, naturalists have hitherto comprehended a systematic arrangement of shells, whether marine, fluviatile, or terrestrial: it is the science by means of which that branch of natural history is distributed into genera and species. The title conchology has, however, been somewhat misapplied, having been used in a less extended sense than its etymological meaning implies; since conchylion does not express a shell only, but the molluscous animal, whose body is altogether protected—merely partially covered

with a shell, or possessing portions of shelly matter, concealed under its skin, or in its folds, to defend certain organs most liable to external injury from their exposed situation. Such of our earlier naturalists as merely studied an arrangement of shells, detached from their parent architect (as was, in fact, the case with nearly all of them), have in many cases, and should in every one, have designated their systems by the term *Testaceology*, which is more appropriate, as not admitting any perversion of the meaning they attached to it, and clearly expressing its derivation and object—*Testa*, the Latin word for a shell; and *Logos*, a Greek word, meaning a discourse or treatise on the subject to which that word is added when descriptive of a science. The Greek writers on natural history also used the term *Ostracology*, which has the same meaning, and is considered by many authors far preferable, not being a compound of two languages, a fault but too frequently observable in the terminology of all works on natural history. Until within about the last half century, nearly every author on this branch of nature has written exclusively on the arrangement of shells, detached from the animals inhabiting and constructing them; this, with very little exception, continued down to the period when the immortal Linnæus, who may be styled the father of systems, among others, formed one of Conchology, but, like his predecessors, it was based entirely on the form of the shell, and his genera composed from the characters it presented. This was done with considerable judgment, and many of his descriptions are extremely accurate, so far as regards external configuration, but in theory, this system is wholly artificial, and consequently bad. It is true he seems to have felt it so to a certain extent, since he has made some reference to the analogous animal which he imagined to have belonged to the shell; these he placed amongst his *Zoophytes*, but he still took no other guide than the form of the shell, and made but few inquiries with respect to the supposed inhabitant. The impulse given throughout Europe by his system, and that of several other eminent naturalists, led to an extended view of the subject; their attention became drawn to the anatomical investigation of the animals themselves; and the subject presented an interest never before experienced; accounts were published of the result of these inquiries, gradually producing a different method of viewing the classification of molluscous animals; and Pallas may be considered the head of this new school, as, in fact, it was from his *Miscellanea Zoologica* that the first germ of improvement was derived in the arrangement of shells, since grown into its present form, though as yet, in many respects, only in its infancy.

Before this, all the systems descriptive of testaceology, were as imperfect as an arrangement of the feathers of birds would have been in ornithology, or the scales of fishes in ichthyology, were writers on these objects of the creation to have confined themselves alone to a systematic arrangement of those parts, without a reference to the animals of which they are merely necessary portions. Cuvier, that great master of nature, feeling the importance of the subject and the want of such an arrangement, directed the vast resources of his giant mind to the accomplishment of the only conclusive classification that can be formed; he improved upon the hints thrown out by previous naturalists; surmounted the difficulties they could not overcome, and was the first to complete a

general systematic classification of shells, built upon an investigation of the animals themselves, in which the families were ranked according to their structure and habit, as far as they were known, or could be safely decided upon by analogous reasoning. Thus, by taking nature as his guide, he has created a system that will stand the test of time as being the most natural, and consequently the best that can be followed. Like every human effort it has its errors, but they are fewer in number, and more those of observation than of theory. Prior to this period little more had been effected than to point out a tolerably lucid arrangement of shells themselves, without any other guide than that of the external configuration they presented, a system perpetually subject to error, because it is not natural, and one which has occasioned the innumerable inconsistencies of Linnæus.

There is no one at all an observer of natural history but will confess, that the apparent freaks of nature, in her productions, are so unaccountable, particularly in conchology, that they never can be depended upon as secure indications, when unsupported by a knowledge of their causes. This can only be acquired by a careful and repeated examination of the animals constructing the shells, and who form their habitations after such a fashion as is best adapted to their wants and security. Nature never oversteps the bounds which the necessary conditions of existence prescribe to her; but, when she is unconfined by these conditions, she displays all her fertility and variety, never, however, departing from the smallest number of combinations that are possible in the essential modifications, though apparently sporting with infinite caprice in all the accessory parts. In these there seems no necessity for a particular form or disposition; it even frequently happens that peculiar forms are created without any self-evident utility. It seems sufficient that they should be possible, that is to say, that they do not destroy the harmony of the whole; in proportion, therefore, as we turn our attention from the important organs of animals, to those whose functions are less so, we discover increasing variations. But when we arrive at the surface of the body, as in shells, where the nature of things requires that the parts least essential, and the injury of which is least dangerous, should be placed, it becomes so considerable, that all the labours of naturalists have not yet been able to give us an account of them. Among these numerous combinations, there are necessarily many which have common parts, and there is always a certain number which exhibit very few differences. By the comparison, therefore, of those which resemble each other, we may establish a kind of series, which will appear to descend gradually from a primitive type; a consideration of these have formed the foundation of the ideas some naturalists entertain of a scale of Being; the object of which is to exhibit the whole in one series, commencing with the most perfect, and terminating with the most simple kind of organisation, or that which possesses the least numerous and most common properties, so that the mind passes from one link of the chain to the other, almost without perceiving any interval, and, as it were, by insensible shades. These observations may generally apply to the study of natural history in all its branches, and is particularly evinced in the classification of shells adopted by modern naturalists, from the structure and organisation of their inhabitants: it constitutes that striking advance in the science,

which distinguishes it from the Linnæan school, in which a knowledge of the animal was not at all studied. In the present state of zoology, the shell and its architect must be coupled together, and Conchology, as it was formerly understood, can no longer, with propriety, express the system it now embraces, and which the French naturalists expressively call *Malacology*, a term meaning *a treatise on soft animals*—a title so satisfactory that we cannot do better than adopt it. Under the article *MOLLUSCA*, we shall more fully explain the principles of the system, at present we will confine ourselves principally to Conchology, in the light it has hitherto been viewed—that of a description of testaceous bodies. It may be well here to observe, that we have indiscriminately used the word mollusc as applied to shells as well as to their inhabitants, throughout all the articles in this work, treating of that branch of natural history. In this we are sanctioned by the authority of several eminent English naturalists.

To persons who are collecting shells and forming cabinets of them only as beautiful objects of creation, the system of Linnæus may answer as well as any other, since they feel no interest in the scientific arrangement of the species, or those wonderful progressions which mark the connecting links of genera, families and species with each other, changes frequently only to be accounted for by an adaptation of parts to necessity. Indeed, were it possible to preserve the animals who have formed the various species, they would present no attraction to the eye, nor add any value to the shells that contained them; but the impossibility of doing this renders the researches and reasoning of naturalists the more valuable. It may, indeed, to mere collectors of shells, appear wholly uninteresting, but a moment's reflection would convince them, that when we attempt to raise a part of the mysterious veil thrown over the works of nature, in order to acquire some knowledge of her laws, we then derive a new satisfaction in contemplating their operations; so that without being ourselves either anatomists, physiologists, or naturalists, in an extended sense of their meaning, we cannot fail of having our attention roused to examine many facts, extremely curious in themselves, which the *shell alone* exhibits, and the mind, once excited into action, seldom rests until it is satisfied. By pursuing a subject to its utmost limit, generally speaking too, the more difficult the task becomes, the more ambitious we are to surmount it. The mind may, indeed, for a time, flag and feel fatigued by over exertion, but such are its elastic faculties, that they may be deemed indefinitely expandable; to say at what point knowledge will stop is utterly impossible, we must not, therefore, reject as useless such portions of it as we cannot immediately understand, but relying on others more advanced than ourselves, endeavour, by every possible exertion, either to corroborate their assertions by our own observation, or, by following the guide given us, to pursue the inquiry still farther. In this point of view, surely the amateur of shells must desire to have his collection arranged according to something like a natural system, and we cannot too frequently impress on the young naturalist's mind, the necessity of observing most attentively the indications so often furnished by nature, many of which are very generally overlooked, and altogether despised as useless, from their being but slightly defined: these are, nevertheless, the natural indices to much

information, and though not in every instance conclusive in themselves, may always be deemed the safest and best guides we can follow in pursuing an unknown tract of inquiry, to which the main road is concealed, or not generally attainable.

The modern systems of Cuvier, Lamarck, and other naturalists of that school, embracing, as we have stated, a knowledge of the animal as the foundation for the classification of its covering, have by many been found fault with on account of the multiplication of genera, which appears to them unnecessary and difficult to comprehend; but such in fact is not the case: on the contrary, the study of testaceology is greatly simplified, and the learner's progress considerably facilitated by confining within a narrower compass the too widely-extended genera of Linnæus, and re-modelling those he had blended together in the most confused manner, whether with regard to the form of the shell and its habitat, or the functions and structure of the animal, a reference to which he merely glanced at. By the information now obtained, from an anatomical investigation of these singular creatures, we are enabled to distinguish between them by certain more or less strongly marked generic characters peculiar to each, and to place their dwellings in a natural series of classes to which this knowledge can alone conduct us. If it be said that the increased number of genera obliges the student to charge his memory with a greater number of sometimes hard names, it cannot much signify, since a knowledge of the whole catalogue can only be acquired progressively. To the disciples of the Linnæan school, the argument still less applies, since they have only to add the newly-constituted genera to those they already know, all of which have been retained by modern writers, only, as before remarked, more naturally distributed, as will be shown under the article *MOLLUSCA*, in which a comparative view of the two schools, and the changes that have taken place, with the reasons for so doing, will be more fully, and, we trust, satisfactorily explained.

We will also here observe, that we have, in some degree, deviated from the beaten path of an alphabetical publication, by including in this article much matter that might more properly be deemed referrible to the article *SHELL*. We have done so in order to render the subject more comprehensive and more readily understood by many of our readers, who doubtless have much to learn before they can derive any pleasure or sound instruction from the study of this branch of natural history in a systematic form. A considerable time must elapse before the article *SHELL* can make its appearance, though various matters relative to it are continually given under their particular head in our alphabetical arrangement; and to those who have not made Conchology their study, many terms technically used to explain portions of the subject, would be incomprehensible, and the science rendered doubly difficult to understand; but by now including a glossary of many terms, established by modern naturalists in the description of parts of shells, their relative position, and their connection with each other,—some account of their growth and distribution in nature,—a rapid view of the history of Testaceology, as we here continue to call it, down to the period when the necessary corrections of the Linnæan system required that change of classification which includes the animals with the shells, the science became more properly designated *Malacology*,—we

think the student's progress will be much facilitated; he will advance, as it were, imperceptibly in the study of this interesting pursuit, till he arrives at, and is capable of understanding the subject in its embodied form of a system. The imperfection of an alphabetical arrangement in publications like the present one will thus be partially obviated, and the tributary information, in a great measure acquired prior to its being consolidated into one mass.

Systems were formed for masters, not for the scholar; for what student would have courage, in the first instance, to wade through a ponderous tome, each page teeming with unutterable terms, to expound which would require the concentrated learning of a polyglot dictionary, and if ever puzzled out, would, many of them (not to say most of them), be found to have but little reference to the thing in question—to give no descriptive assistance, but to have been coined from the author's caprice or particular view of the object before him. Let us not, however, be understood as finding fault with the necessary scientific nomenclatures established by long usage: did they not exist, it is obvious that the simplest object could not be explained without great circumlocution; neither can we object to their being expressed in the most universal language known—the Latin tongue, since a knowledge of that opens the high road of mental communication with all the civilised nations of the world, enabling scientific men to converse and interchange their ideas or opinions, though living distant as the poles asunder. But we do seriously deprecate the affectation some authors exhibit of displaying unnecessary erudition in their nomenclature—of applying profound learning to trifling objects, and, what is worse than all, of giving names and terms that have no reference whatever to the subject matter; this needlessly embarrasses the student, by leading him far out of his road, and a name which should assist him like a sign-post on his way, pointing out the shortest path to some other place of inquiry, becomes his greatest impediment—of no use whatever, if not understood, and if comprehended, is perhaps not at all explanatory of the subject. An opposite species of affectation has been recommended by some modern writers in this country, that of anglicising all terms of science. But it is quite impossible so to simplify scientific study, as to do without a generally-received nomenclature in some language or other, and, as we have just observed, the Latin, from its universality, is the best of all others; but let every newly-coined term be strictly confined to its plainest expression, and its meaning always explanatory of the object to which it is applied: without this is attended to, it is “fighting flies with spears.” A system is a completion of the whole subject, and can no more be properly understood at first sight than a watch or any other complicated piece of machinery depending upon its subordinate parts for the production of one perfect result; it must be studied step by step, and the more easy the path is rendered by removing difficulties, the more inviting the progress will become. Cuvier observes, “that the formation of systems is the object of natural history, properly so called. Anatomy receives them as it were ready made. The latter takes its first direction from the former, but it is not slow in reflecting back the light it has received. By applying a system of natural history to comparative anatomy, we are speedily enabled to discover whether it deviates from the path of nature. The object of every good method

is to reduce a science to its simplest terms, by reducing the propositions to the greatest degree of generality of which they are susceptible. A good method must therefore be such as will enable us to assign to each class, and to each of its sub-divisions, some qualities common to the greater portion of the organs. This object is to be attained by two different means, which may serve to prove or verify one another. The first, and that to which all men will naturally have recourse, is to proceed from the observation of species to uniting them in genera, and to collecting them into a superior order, according as we find ourselves conducted to that classification, by an examination of the whole of their attributes. The second, and that which the greater part of modern naturalists have employed, is to fix beforehand upon certain bases of division, agreeably to which beings, when observed, are arranged in their proper places. The first mode cannot mislead us, but it is applicable only to those beings of which we have a perfect knowledge; the second is more generally practised, but it is subject to error. When the bases that have been adopted remain consistent with the combinations which observation discovers, and when the same foundations are again pointed out by the results deduced from observation, the two means are then in unison, and we may be certain that the method is good.”

Many whom we unhesitatingly call ignorant persons, not knowing the benefit mankind has derived, and must yet reap, from the study of natural objects, overlook totally, or but lightly value the wearisome preliminary steps—the never-ceasing patient investigation by which these advantages have been acquired, this knowledge gained. Such persons have considered Conchology particularly, as undeserving the rank of a science, its study beneath the serious attention of a highly-cultivated mind, and affording nothing beyond the gratification attendant on the possession of pleasing objects to the eye, or to that vanity which frequently springs from the exhibition of an elegant and costly taste, not attainable by our less fortunate neighbour. To them let it be said, that the contemplation of objects created by Him whose beneficent wisdom caused all these things to be; of Him who has formed nothing in vain; of Him who in “six days made the heaven and earth, the sea, and all that in them is,” cannot either be useless or beneath the dignity of the most enlightened man, the utmost extent of whose education can only teach him how little he can ever know of all that is yet to be learned. In natural history especially, we are always to a great extent dissatisfied with whatever we perform, for nature proves to us at every step that she is inexhaustible; but this, nevertheless, augments our enjoyment, as we proceed onward in our pleasing task—as each difficulty is surmounted, a new impulse is given to our exertions, till we are ultimately rewarded by being able to read the book of nature in its proper language. Happily, the researches and writings of some few scientific men have of late years given a zest to the study of natural history never before experienced, by clothing it in the simple language of truth, enabling us, while cozily placed by our fire-sides, to wander in imagination through the scenes they so glowingly describe. We live for a time in every country; in every clime, we seem to travel along with them in their sometimes perilous journey, to share their dangers, and to participate in the satisfaction of having surmounted them. Who can read works like those of Audubon, Water-

ton, Wilson, and many others, without feeling all this, and much more? And though some twinges remind us that years have rolled their weight upon us since we brushed the morning dew, we are nevertheless carried back to the halcyon days of youth, when, as we bounded through the daisied mead, all nature seemed decked in never-fading beauty, by such writers, the rich, the marvellous storehouse of nature is opened, her treasures displayed to our eager view, and from "nature we look up to nature's God." It has been gravely asserted, that wretched beings have existed, called Atheists, and that the investigation of nature's works has led to infidelity in some persons. We doubt the existence of the one, and utterly deny the possibility of the other; but should such a species of frenzy for a moment obscure the light of reason, paradoxical as it may appear, we fearlessly prescribe, as the only certain cure, the very supposed cause of the malady; and say, let the sufferer apply himself fearlessly to the study of natural history, in all or any portion of its branches, believing, as we most conscientiously do, that a good naturalist can never be a bad man. Conchology, it must be confessed, does not, unfortunately, present all those inviting charms in its study that the other portions of the creation do. We cannot become intimately acquainted with the habits and manners of creatures inhabiting the profound depths of the ocean, in which the works of nature, generally speaking, are more known by accident than any other source of information; where, too, no regular train of reasoning, from an observation of these animals in their native element, can be pursued, beyond that afforded by an examination under the most unfavourable circumstances, of a very small portion of the teeming myriads that exist unseen; and until the endless ingenuity of man shall have invented some sub-marine mode of conveyance—some omnibus, that will transport us safely and speedily to the nethermost pole and back again, enabling us to travel in "that world that lies below the now smooth and glassy surface of the deep, and the now wild and tremendous action of its waters, to contemplate the varied forms, qualities, and habits of its animated tenants, their subjection to man, and their subserviency to his use," or to realise the poet's dream, by beholding those scenes—where

The floor is of sand, like the mountain drift,  
And the pearl shells spangle the flinty snow;  
From coral rocks the sea-plants lift  
The boughs, where the tides and billows flow;  
The water is calm, and still below,  
For the winds and waves are absent there;  
And the sands are bright as the stars that glow  
In the motionless fields of upper air;  
There, with its waving leaf of green,  
The sea-flag streams through the silent water.  
And the crimson leaf of the dulse is seen  
To blush, like a banner bathed in slaughter;  
There, with a light and easy motion,  
The fan coral sweeps thro' the clear deep sea;  
And the yellow and scarlet tufts of ocean  
Are bending like corn on the upland lea,  
And life, in rare and beautiful forms,  
Is sporting amid those towers of stone,  
And is safe when the wrathful spirit of storms  
Has made the top of the waves his own;  
And when the ship from his fury flies,  
Where the myriad voices of ocean roar,  
When the wind-god frowns in the murky skies,  
And demons are waiting the wretch on shore,  
Then far below, in the peaceful sea,  
The purple mullet and the gold fish rove,  
Where the waters murmur tranquilly  
Through the bending twigs in the coral grove.

PERCIVAL.

Till all this can be witnessed personally with as much ease as we can depict them mentally, our pro-

gress in acquiring a perfect knowledge of this science, in its extended sense, will necessarily be extremely slow and uncertain. We must depend principally, if not altogether, on the information derived from authentic sources. This we should confirm by every possible opportunity, neglecting nothing likely to assist our doing so, however insignificant it may at first sight appear. More is really learned by the application of common sense, though only to a limited extent, than all the systems written could impart to *beginners* in the study of natural history; for, by actively exercising our reasoning faculties, we determine, upon the strongest grounds of rational deduction, many facts but slightly defined, or wholly invisible.

We have not, most of us, the opportunity of examining with our own eyes some of the molluscous animals that are within the reach of other persons, many of whom, unfortunately, know not how to benefit from the opportunity; we are therefore compelled, in numberless instances, to take for granted every traveller's tale, until the truth or fallacy of it is confirmed by subsequent information; but so inherent is the vice of fiction, that very little reliance can be placed upon many of the strange sights they see. Mankind is also so fond of novelty, or whatever partakes of the marvellous, that the every-day's observation of nature's operations is neglected; we are even too indolent to examine and reason for ourselves; we prefer gleaning imperfect ideas from fanciful accounts of nature, in our closet, to the delight of, perusing her works in the rich volume every field opens to us. This obviously leads to the erroneous conclusions entertained by book-naturalists and book-makers, among which are some (and those, too, professing to instruct the rising generation) who have recently published a poetical description of certain shells sailing together in little fleets—one valve expanded to catch the passing breeze that wafts them o'er the unruffled bosom of the vasty deep—of others that may be supposed to pass their leisure moments in playing at leap-frog with each other. But these, like all other tales conjured up by the magic wand of fancy, are more entertaining than true, and must be condemned in works whose object should be to clothe facts in the simplest garb, divesting them of the tinelled ornaments of fiction, which, though they may dazzle for a time, shortly sink before the light of truth, and are rejected as worthless. Another serious evil arises from these pretty nursery tales, that of casting a doubt upon every other assertion, however well founded in truth.

An instance may here be adduced of the ease with which some of the interesting operations of nature can be witnessed in the portion of creation now under our consideration, and amply repay us for the trouble. It is afforded by the humble, persecuted, but most beautiful of our native molluscs, the snail (*Helix nemoralis*), the little creature we barbarously crush beneath our feet, considering it a common enemy to horticulture. When we examine its wonderful formation, its tenacity of life, its reproductive powers, an instructive lesson may be furnished to the conchological student, most satisfactorily explaining the growth of the vast proportion of similarly constructed shells in other genera, and enabling him to understand by actual observation, and the evidence of his own reason, some of nature's steps in this branch of her works; he may easily watch the various changes that take place from the slight viscous covering with

which the animal's body, in the first instance, is coated, or, as it were, merely glazed, till that substance becomes a consistent firm shell, finally fashioned into a painted palace adapted to the form and use of its inhabitant. It needs no logic to prove, that wherever creatures are endowed with a long endurance of life and great reproductive powers, great purposes are assigned to them. The condemned snail does not, therefore, merit the ill treatment it constantly experiences from man; and if we for a moment reflect upon its good services, and overlook its bad ones, we are bound to confess the former greatly outweigh the latter. It is viewed as a destructive marauder in our trim gardens; but we forget that we have invited its inroads by placing, within a comparatively limited space, a choice selection of dainty food even to the pampered appetite of man, but altogether irresistible to a snail. In the open fields, or the widely expanded forest, this little creature performs useful purposes in conformity to the ends of its creation; one of the most important of which is that of assisting in consuming the exuberant productions of nature, which, without its operations, would encumber the surface of the globe, check the progress of future vegetation, and interrupt that perpetual harmony of system, which has wisely ordained that the extinction of life shall not be felt, but its devastations become supplied by succeeding generations, each of their kind, whether vegetable or animal. In countries where vegetation is too luxuriant to be trained by art to the use of mankind, covering immense tracts of land with impenetrable gloom, not only snails, but other species of terrestrial molluscs, *achatina*, *bulinas*, &c., are found, some of a very large size, proportioned to the magnitude of the duties they have to perform, and in these situations their voracity is said to be most extraordinary—stripping the loftiest trees of their verdure in an incredibly short space of time. Shall we then grudge it a slender portion of our superfluous luxury, without ascertaining, by actual examination and rational reflection, that this little creature was not merely ordained to devour our choicest fruit, but that it has also a duty to perform by consuming, in a far greater proportion, other things in the vegetable world that would, without them, prevent the full completion of the very object for which we ignorantly destroy a principal agent.

The well-established fact, that the eggs of these animals have been absolutely baked, during six months, under the scorching rays of a tropical sun, without destroying the germ of life, proves, could no other facts be adduced, that nature has vested in these creatures certain important uses and powers far beyond our short-sighted views; and it must lead a philosophical mind to conclude, that in this instance, as well as in many others equally remarkable, we stubbornly close our eyes to the good that is forced upon us. We think we hear it said, that in advocating the cause of snails, we have never had the mortification of seeing our ripe and delicately-painted peaches disfigured by their hungry propensities. Be that as it may, we have also observed, that they, like ourselves, when no such treat presented itself, were content with humbler fare, and as industriously as voraciously consumed other objects, to us useless, or noxious as food, never deserting the purpose of their existence, though that end is not yet fully revealed to us. As an article of food, they are entitled to our consideration; for, though they form no part of our gastro-

nomie delicacies, they nevertheless were considered such by the Roman gourmand; see *AMPULLARIA*; and even down to the present day, snails form an important article of nourishment and commerce in Germany, France, Spain, Italy, Turkey, and the Levant. This digression leads to a conclusion, constantly to be drawn by every reflective mind, that from the colossus of bivalves (the *Tridacna gigantea*) whose inhabitant would satiate the "sharp-set appetites of an hundred men," down to the shell less than a grain of sand, each is endowed with similar mechanical powers and bodily faculties, adapted to its sphere of action in the place it is destined to occupy, the one and the other playing an equally important part in this crumbling theatre of mortality, and forming so many connecting links of the chain that binds together the invisible operations of nature under the directing wisdom of Omnipotence.

We hope to be able to point out many useful, as well as pleasing results, derived from the study of Conchology, and to give an interest to it beyond the commonly-received opinion of it. In the first place, it is inseparably connected with geology, or the formation of the earth, and a study of the one must necessarily contribute to a more perfect knowledge of the other, since shells, from a period before time was, have constituted so large a portion of the earth's matter. In their fossil state they have been eloquently called by a late writer the only *true medals* of creation now extant. He says, "by these medals we are taught that innumerable beings have lived, of which not one of the same kind does any longer exist; that immense beds, composed of the spoils of these animals, extending for miles under ground, are met with in many parts of the globe; that enormous chains of mountains, which seem to load the surface of the earth, are as vast monuments, in which these remains of former ages are entombed; that though lying thus crushed together in a rude and confused mass, they are hourly suffering those changes by which, after thousands of years, they become the chief constituent parts of gems, the limestone which forms the cottage of the lowly peasant, or the marble which adorns the splendid palace of the prince."

To this may be added, that the local indications they furnish enable us to ascertain, with a considerable degree of precision, the identity or the superposition of the different strata of the earth's formation, to distinguish between the various geological changes of the antediluvian world, and to account philosophically for many of those natural phenomena which the mutations of this planet have produced, changes which, without some knowledge of conchology, must have remained, if not altogether unaccounted for, at least less easily understood. Indeed, it is to geologists that we are indebted, in a great measure, for having rescued conchology from the obscurity into which it had nearly fallen as a science. The extremely minute characters existing between fossil shells, or between them and recent species, required an extended knowledge of the subject, including the structure of the animal, as well as its dwelling; and it consequently became necessary to establish something like well-grounded principles and given rules to guide them in their delicate researches, or to assist in resolving the extremely difficult problems they have undertaken to explain. To the physiologist and anatomist, a study of the animals, the architects as well as inhabitants of these beautiful productions of

nature, presents an interest beyond the mere scale of enjoyment which a contemplation of them enlarges. It leads him, by analogous reasoning in comparative anatomy, the more clearly to understand some of the laws and economy of animal life, and to account for many of those paradoxical causes of vital existence which these inferiorly organised creatures illustrate.

Of the benefits derived by mankind from shells, or rather their animals, less is probably known at this moment than could be wished, or might be expected; they will only be developed by time. As articles of food, numberless species are well known. We need scarcely mention the oyster, for which our native shores have so long been famous; since, so far back as the beginning of the second century, the Roman poet Juvenal, while satirising the epicure Montanus, thus speaks of them :—

"He, whether Circe's rock his oysters bore,  
Or Lucrine lake, or distant Richboro's shore,  
Knew at first taste."

These, with muscles, cockles, scallops, &c., form a considerable branch of commerce and wealth to the enterprising fisherman; an account of which will be amply given in the alphabetical arrangement. Many other species of shell-fish might also be enumerated, affording an agreeable and nutritive food to nations compelled by local situation, uncongenial climate, or ignorance of civilised improvement, to seek from ocean's bounteous store, a natural and never-failing source of subsistence, frequently, indeed, the principal, if not the only one within their reach. In the days of Roman epicurism we have already enumerated snails and oysters, to these may be added *Echini* and *Balani*, for we are told, that at the famous supper given by Lentulus when he was made Flamen Martialis, or Priest of Mars, these and other shell-fish formed a part of the delicacies presented to the guests; and Pennant satirically observes, they seemed to have been eaten by the holy personages, priests and vestals, invited on the occasion, as a *whet* for the second course. The *Echinus*, however, is a crustaceous and not a testaceous mollusc, as we shall explain under its description: we have tasted both this and the *Barnacle*, but not possessing Roman stomachs, or perhaps from the want of classical cooks, we confess they appeared anything but eatable to our vulgar taste. As baits to catch fish, many species of shells are used; we have, ourselves, captured many a bright mackerel and whiting with no other lure than a small piece of mother-of-pearl suspended from the hook. The amphibious mammalia, sea-birds, and even many fishes, derive a large portion of their sustenance from shell fish, which tends to check, without destroying altogether, the innumerable broods hourly brought into existence. Except as food, shell-fish contribute but little to supply the other wants of mankind. The *Pinna marina* does, it is true, furnish with its byssus, or beard as it is commonly called, a silky filament, in sufficient abundance to be fabricated into gloves, stockings, and some few other articles of wearing apparel, but not in such quantities as to render them articles of general use, or commercial speculation, beyond the value attached to them as museum rarities. The *Janthina*, *Buccinum*, and other shells, indicate the presence of a strong colouring matter, and a species of *Purpura* produced the highly valued Tyrian purple dye, which formed a very costly article in the catalogue of Roman

extravagance; but the same colour being now obtained by the chemical effects of mineral or vegetable matter, at a trifling expense, has, of course, superseded its use. In early treatises on medicine, shells ranked as useful agents; they, however, now form no part of the pharmacopœia, common chalk being equally efficacious. In countries where the manufacture of glass is either unknown or too expensive to be generally used, a shell of the genus *Placuna* is substituted to the present day, its extremely thin valves permitting the rays of light to pass partially through them. With these, in China and Japan, the windows may be said to be glazed. As a commercial circulating medium, shells have been employed on the coast of Africa, where sealed bags of the *Cyprea moneta* (money cowry) form tallies for certain sums; thus exchanging hands in the trading operations of uncivilised nations, as an equivalent for coin, and redeemable by the party issuing them with the same good faith that notes are honoured by the firm on which they are drawn. As articles of luxury and decoration, shells, from the most remote period of history, have afforded personal ornaments, in various ways, to civilised and savage people. With some they are distinctive marks of rank, and in the idolatrous worship of India, some species are consecrated to ignorant superstition, by those "who sit in darkness and who see no light." The *Avicula margaritifera*, commonly called the mother-of-pearl oyster, is universally well known as yielding that beautiful iridescent substance, from which numberless elegant and useful trinkets are fashioned by skilful workmen. It must be observed, however, that the beautiful colours, like those of the *Opal*, which they resemble, are not the effect of any pigment or colouring matter, but occasioned by the mechanical arrangement of the molecules, or atoms of matter, constituting the lamellar substance of the shell, being so distributed as to become capable of decomposing the rays of light, and reflecting the exquisite prismatic hues which all pearly or nacreous shells exhibit. On this subject the philosophical experiments of Brewster and others are highly interesting. It is the animal of this shell, or a diseased condition of it, which produces that modest but highly coveted jewel, the Oriental pearl, the pride of Europe's fairest daughters, or Africa's sable children—the gem that decks a monarch's brow, or graces native innocence. In sacred writing, pearls are frequently named as things of inestimable value. "No mention shall be made of coral or of pearls, for the price of wisdom is above rubies," and in Matthew, our Saviour said, "The kingdom of heaven is like a merchantman seeking goodly pearls, who, when he had found one pearl of great price, went and sold all he had and bought it." Poets of every nation, but particularly those of the eastern nations, have compared the objects of their dearest affections to pearls, as the most invaluable things known, its Persian name *Mervarid*, or globe of light, being constantly used in the hyperbolic language of oriental poetry. Our native poets have also, frequently alluded to pearls; upon the latin name of which (*Margarita*), Drummond, in his poems, 1656, classically puns in the following lines—

In shells and gold, pearly are not kept alone,  
A Margaret here lies beneath a stone;  
A Margaret that did excell in worth,  
All those bright gems the Indies dothe send forth.

Several other species of shells, both marine and

fresh water, also produce pearls—the *Pinna marina*, *Tridacna gigas*, *Unio*, *Mussel*, &c.; they are, however, far inferior in beauty and value, though Suetonius informs us that the pearls found in Britain were so highly extolled at Rome, that they mainly influenced Cæsar's invasion of our sea-girt isle, and though his ambitious views were only in part realised by the attempt, he did not lose sight of one of the inducements which led to it, and a buckler, richly decorated with British pearls, was placed on his return, in the gorgeous temple dedicated to Venus Genetrix, as a trophy of his mad ambition, and an imperial offering worthy the sea-born goddess. The rivers and seas of Ireland, Wales, and Scotland still yield pearls; even to a late date fisheries of them have been established, but the produce is comparatively of so little value that it no longer repays the speculator. A remarkably fine Welsh pearl is said to have been presented by Sir Richard Wynne, of Gwyder, to Catharine, Queen of Charles II., and still to hold its place in the regal crown of England.

In the alphabetical arrangement of this work, pearls will be more amply described, and an account of the Oriental pearl fisheries given.

Having enumerated some of the known benefits mankind derive from shells, whether as food, ornament, or otherwise, it will be proper to point out such as are injurious, or so considered in certain points of view, that is, so far as their habits tend to defeat the industry or ingenuity of man; but here, as in the instance of the common snail, we feel called upon to enter a philosophical protest against treating them indiscriminately as destructives and enemies. The evil they commit is certainly manifest, but it is confined to a very limited circle—it may be everywhere checked, or prevented by care or art—while the good they perform, being unseen and extended over an immense space, passes unheeded, and, in the present stage of our knowledge of natural history, is not appreciated as it should be; let it, however, be remembered, that there is an eternal fitness of things which requires that the decrease of various portions of creation should, in some degree, keep pace with their otherwise superabundant growth, thus balancing the account of nature's dealings, and regulating the expense of life. Extensive mischief is doubtless committed by that insidious little animal the *Teredo*, which recklessly wends its way in ten thousand tortuous paths, through the hardest oak, or toughest teak, rendering them like sponge, and destroying their texture as supports to submarine erections, occasioning, in certain localities, dangerous consequences; piles, jetties, piers, and vessels, long stationed in some climates, are subject to their ravages, from which fatal accidents have resulted. It is not in human nature thus to witness the destruction of the noblest works of our ingenuity, without condemning the agents that have effected it; but these are no more than additional illustrations of the fact, that it is for man's ultimate benefit such occurrences should take place—they give a stimulus to his industry—set his wits to work—teach him to counteract the evil committed against his immediate interest or convenience, and often create a far greater eventual benefit than he could at first sight discover. The wise man only becomes so by not despising the humblest information, he is constantly examining, inquiring, or reasoning on everything around him; and some of the greatest efforts of genius have been perfected from the indica-

tions furnished from apparently trivial causes, overlooked at first from their insignificance. Another of the number of shells but little loved by mariners, is the *Balanus* or *Barnacle*, whose numerous broods spread themselves in thick congregations, sometimes as it were incrusting the bottoms of ships, and their sides below the water mark, to such an extent, that her progress through the pathless sea becomes seriously impeded: the watchful sailor baffled in his best exertions, and the wealthy speculator disappointed in his nicely calculated hope of gain. To conclude our list of commonly called destructives in conchology, we shall add the *Pholas*, and other of the penetrating genera of shells, whose habitations are formed in calcareous, and even stony matter, wood, &c., there performing either good or evil according to the particular circumstances of their situation and the purposes of their being, which are, if well considered, probably more beneficial than prejudicial to mankind.

Shells are abundantly distributed over every part of the globe, from the polar regions to the torrid and inter-tropical zones, increasing in number, size and colour, as they recede from the one and approximate the other, a fact equally to be observed in the other works of creation. Heat and light, as we shall hereafter explain, possess such a prodigious influence on these productions, that the most beautiful, whether marine or terrestrial, are those inhabiting tropical climates. It may be said, that no part of the world is divested of shells, either terrestrial, marine, or fluviatile, and the number of their species is always proportioned to the extent of their peculiar location or habitat; we may also ascertain that nearly all the families exist in the different zones of the globe, though the genera and species of some are far more numerous in one zone than in the other. To attempt a detailed account of the geographical localities of the different genera, would not only be extremely difficult, if not totally impracticable, but would occupy a larger space than can conveniently be allotted to the subject in a work like the present one; we will, nevertheless, point out a few leading facts with regard to the habitat of shells, which will serve as a general illustration of the localities of their congeners. In the high northern latitudes shells are not numerous, and the species most usually found are of the genera *Terebratula*, *Mya*, *Pandora*, and some of the *Solen*; they are not, however, equally abundant in all the northern seas. The *Ostrea*, *Avicula*, *Orbicula*, *Crania*, *Terebratula*, *Halotis*, *Pecten*, *Patella*, *Arca*, *Lima*, *Maetra*, *Pholas*, *Balanus*, *Cardium*, *Teredo*, and *Helix*, are everywhere found in greater or smaller numbers, as the degree of latitude varies; the *Clavagella*, *Aspergillum*, and *Fistulana*, appear confined to the equatorial zones; the *Vulsella*, *Perna*, *Chama*, *Crenatula*, *Trigonia*, and some of the *Cardia*, inhabit the southern zones; the *Harpa*, *Terebra*, *Cassia*, *Pleurotoma*, *Maetra*, *Strombus*, *Conus*, *Oliva*, *Ovula*, *Cypræa*, &c., principally inhabit the inter-tropical regions; the *Tridacna* has not yet been met with anywhere than in the Indian archipelago: the *Argonauta*, *Nautilus*, and *Spirula*, mostly dwell in the torrid zone. With respect to terrestrial species of shells, it may be observed generally, that they are more numerous—higher coloured, and of a larger growth, in the southern and eastern regions, than in the northern and inter-tropical. Our *Helix nemoralis*, field snail, is, however, a remarkable exception, as its colours vie with those of its congeners in any other country, and

in point of size, some species of European *Helix* exceed those of the warmer latitudes; the *Testacella* may be said to live almost underground; and hot springs, and the bituminous waters of the Dead Sea, are not without testaceous inhabitants. Extremely interesting conclusions will, sooner or later, be drawn, as the science of malacology becomes better understood; respecting the diminution of species, the limits of their variations, and to what extent the individuals are modified by local circumstances in the places they inhabit. Many shells are of a very large size, while others are invisible to the eye. In the formation and arrangement of collections of shells, merely as objects of natural beauty, they cede to no portion of nature's productions; and, unlike every other branch, they possess this immense superiority, that with a very moderate degree of care, they may be preserved comparatively uninjured for centuries, losing nothing of their substance, and but little of their colour.

How truly the naturalist, Pliny, says—"What can be more wonderful than to view nature in all her irregularities and sports in her variety of shells; such a difference of colour and of figure do they form, flat, concave, long, lunated, drawn round in a circle, the orbit cut in two; some are seen with a rising on the back, some smooth, some wrinkled, toothed, striated, the point variously intorted, the mouth pointed like a dagger, folded back, bent inwards! All these creatures, and many more, furnish at once novelty, elegance, and speculation. While I thus contemplated nature, she wrought in me a persuasion that I should look upon nothing as incredible that related to her." What, indeed, can surpass the freaks and vagaries exhibited by nature in this portion of the creation? For, whether we admire the graceful symmetry of some, or the grotesque deformity of others, the delicate sculpture, or the rude furrows, the exquisite pencilling and vivid tints, or the bold marking and sombre hue of shells, we are lost in admiration, and the contemplative mind is roused to adore the infinite wisdom that has called all these creatures into existence, and the interest they excite induces us to attempt in some degree to account for their uses. Thus conchology is raised to a more important rank in the march of intellect than it has hitherto occupied in public estimation. We hourly begin to develop new features in its study leading to philosophical results never before contemplated; and though our progress is so much restricted by circumstances, it will be rendered the more secure from being progressive, and founded upon repeated observation; we are involuntarily led to assign causes for the effects, and some insight is gained into phenomena that at a first glance appeared most marvellous. Marvellous in truth they must always remain as regards the power and wisdom that gave them life, and invested them with given functions in the scheme of creation. It is, however, to their mechanical structure, if we may be allowed the expression, that our remark applies. In this the exercise of that most invaluable of all gifts, common sense, combined with the tolerably accurate observation of our visual organs, is all that is necessary to those who have not had the additional advantages of an education directed to the improvement of these observations upon anatomical data. This is, however, of the less importance in conchology, treating it, as we now do, as a separate science, and solely applicable to shells, in which point of view nine-tenths

of our readers will value it, if they value it at all; but they must not forget that, as a science, it is most incomplete, imperfect, and artificial; if the animals themselves are not to be studied in connexion with their coverings, for they ought not, and cannot properly be separated, without violating every principle of natural history, and rendering this branch no more than a classification of differently-shaped pieces of carbonate of lime.

It being demonstrable that shells are formed on the model or naked body of the animal constructing them, every portion or inequality of surface these bodies present must necessarily cause either depressions or protuberances on the exterior of their shells corresponding with them; whereas, in the simple snail, these do not exist, or in other shells which have only little elevated knobs, or regular grooves, bands, &c., we easily may conceive how the surface of the shell corresponds with the exterior of the animal's body; and when we examine shells constructed like the *Scalaria pretiosa* (Wentletrap), or the *Harpa* (Harp), and others of a similar character, we observe the covering of an animal whose periodical increase is distinctly marked by the lip or termination of each addition to its original size. This forms what may, for the sake of description, be termed ribs, when placed longitudinally from the apex to the base, as in the *Harpa*, or rings, as in the *Scalaria*; and here we only want the opportunity of ascertaining the time occupied in constructing each of these additional portions, to determine the age of the shell. This remark also applies both to bivalve and univalve shells. But when we examine a shell set with spines, or foliated processes, we for a moment hesitate to believe that such was formed in the animal's body; and here the exercise of common sense is necessary to explain, in the absence of the animal, that which appears inconsistent with the theory laid down; our reasoning faculties are called into action, and we observe, that in the early stage of growth, many species of shells differ widely from their mature formation, many instances of which may be named in the genera *Strombus*, *Pteroceras*, *Ranella*, *Cypræa*, &c., not to mention numerous bivalve shells whose valves are variously provided with spines, arched scales, &c. When such are met with, it is obvious that their formation has been caused by the necessity the animal feels of having certain corresponding organs protected, either wholly or partially. In the first period of growth, these organs, not having reached the full term of their development, the shelly matter extended no further than was required, for nature, in her operations, never squanders the materials she employs to carry them into effect; she always adopts the shortest way of going to work, having no ulterior object to guide her course than necessity; but that hard taskmaster never drives her from an uniform progress. Combined with the strictest economy both of time and matter, everything in creation hastens on, by regular stages, to its utmost state of perfection or maturity—there stops—ever after sinking into gradual decay. The purposes of its animal existence daily become more feeble, till they are altogether extinguished by death. Thus, in the genera we have just named, the claws, spiny processes, or terminal bands, could not have been formed from a calcareous deposit on the body of the animal, properly so called; but we can easily account for their formation, particularly if we have the advantage of examining the young and the adult shell at

the same time. In the *Pteroceras*, here figured, for example, the young shell, instead of the elongated

Adult Shell.

*PTEROCERAS SCORPIO.*

points, has open, waved prolongations, which, as the organs they then covered increase in length, become lengthened, and finally closed altogether, as the animal, after attaining its maturity, finds it no longer necessary to go on building, but then retreats into its dwelling, and the very organs most serviceable to complete it not being any longer in constant action,

*Murex tenuispina.*

cease to grow, and, on the contrary, diminish in size, and very frequently disappear altogether. In other

genera, the *Murex*, &c., we see regularly-formed sets of spines, or foliations, at given intervals, round the spiral form of the shell. Each of these, it is quite clear, formed previous terminations, and became successively closed as the increased size of the animal required more room. These additions go on with the greatest regularity, and correspond accurately in all the species, with the exception of some few, which may be considered sports of nature, and not generic distinctions. By counting these periodical additions, we come to the same conclusion regarding their age as with the Wentletrap. We can indeed say that such a shell is not an adult one, by counting the number of varices, but it has not yet been determined what period of time is necessary to complete the standard measure. *Hélices*, and their congeners, never form a thickened lip until their full growth is attained. Double-lipped shells have been described, but they are extremely rare. We shall point out the mode adopted by nature in forming the snail shell, in which it will be seen, as before stated, that it is formed on the animal's body. It is equally certain, though not so easily proved by observation, that those shells which have claws, as they are termed, such as the *Pteroceras* present, or foliations and spines, as the *Muriceæ* exhibit, must depend wholly on the form of the skin of the mantle and its age, by means of which these were formed, its lobes, prolongations of portions of the mantle, the organs of respiration, the head, oviduct, &c.; each producing, by their habitual uses, the spines, claws, canals, and other parts of the external covering of the animal. If the edges of the mantle of the animal are even, the termination of the shell is the same; if waved, so is the external edge. Where digitations of the mantle exist, they are equally protected, and become, as we have stated, claws or spines; tubular in their early growth, but rendered solid by repeated deposits of testaceous matter, exuding from the mantle in certain proportions, till the period of its full maturity. The animal then declines; its dwelling is sufficient for the protection of its body; the wants of its life in seeking food, or in moving from one spot to another, during the completion of its growth, require an extension of those parts, at first but slightly defined, and they are not in the full exercise of their adult functions; but these extended organs in youth are much greater in proportion, and frequently more numerous, than they are in the stage of decrepitude, when they begin to disappear, and the activity of their offices gradually decline, being no longer required to complete most of their destined operations. As a general deduction, we repeat, it appears quite certain that the spines, tubercles, and claws of shells, however solid they may be met with, have all of them, at first, been channelled or grooved, to defend certain exposed organs in those which have the canal or slit on the under side, and they are by far the most numerous, having been produced by the digitations of the mantle; while those which have the slit on the upper side, as in the *Purpura* and *Venus Dione*, (Linnæus) appear, on the contrary, to have been produced by the concavity of an appendage to the mantle, which projected on the outside.

Nothing certain appears known of the age of shells, though we have just remarked that certain stages of growth are marked by signs of the shell being then finished; their growth probably in many species, under favourable circumstances of climate

and food, continues for a definite period; with regard to the animal, whose increase of bulk requires increased accommodation in its shell, as would appear particularly in the genera we have already named, and in all the other genera whose varices, whether spinous or foliaceous, seem placed at stated intervals, some being found at the half turn of the whole circumference of the shell, others at a quarter, some one third, and some perpendicular to the base; others at the sides of the shell, giving it a flattened or ventricose appearance, according to the position of these previous terminations, which, it must be again observed, are formed of the vitreous, and not lamellar substance. In bivalve shells, also, the period of growth may be traced by their striae, and they seem also to have a limited extent of increase, as, generally speaking, the various genera attain a tolerably uniform size. Their age is, however, more strongly marked by the thickness of the valves, and the internal muscular impressions, than any other guide. The valves of shells having a continual tendency to fly open, in consequence of the elastic ligament situated at the side of the hinge, which operates as a muscle, it was necessary that the animal inclosed should have the power of closing them at pleasure. There are, therefore, according to the different genera, always one or two muscles fitted for this purpose. In the oyster there is only one muscle of this kind, situated near the centre of the shell, behind the liver, and in the middle of the cloak. It is inserted into both valves, and by its contraction brings them together with an astonishing force, equal to the pressure of many hundred pounds weight. The same mechanism prevails in the *Perna*, *Avicula*, and *Spondylus*. In young shells these muscles leave a fainter impression than in old ones, in which the increased substance of the valves render them deeper. They are, as it were, always advancing more towards the edge of the valves, not that these muscles are ever displaced entirely, but new portions of them are formed as the animal finds it necessary to occupy a convenient position in its dwelling; the posterior parts of the muscle become inactive, and die away, whilst others replace them on the anterior part, and so on during the life of the animal. These muscular impressions also afford an excellent guide to the genus of animal to which a shell belongs, where no other opportunity presents itself of judging. The difference which exists in the size of shells of the same species, particularly in such as have not the strongly marked lip, or other final termination, is very remarkable. It does not appear easily accounted for, but a similar anomaly exists in every branch of natural history; and it may therefore be attributed chiefly to the strength and constitution of the animal, being always proportioned to the favourable or unfavourable situation of its habitat, and the goodness of its nourishment in peculiar situations. Another extraordinary occurrence is, the elongation of the spires of some univalve shells, in which the whorls do not touch each other, but appear drawn out like a coiled spring. The *Scaloria* and *Helix* are those in which that lusus has been observed, though it is very rare; but the greatest monstrosity of all, the most inexplicable freak of nature, is displayed in such shells as are sinister or heterostrophe, that is, having their whorls turned to the left instead of the right. This can only be accounted for by the viscera of the animal presenting a change in their

position, which of course is followed in the formation of the shell, this is to be understood, but the former baffles inquiry. Such a phenomenon might therefore occur in every species of mollusc, and does so in numerous instances; but some of the genera, particularly of terrestrial shells, are more commonly left-handed than on the contrary. These, however, do not, in the opinion of the author of this article, constitute anything beyond a variety or sport of nature, though constantly occurring in some genera.

The probable number of shells in a recent state, can only be guessed at; as, in addition to the species already known, naturalists and travellers are continually increasing the amount by new researches; but judging, which may fairly be done, from the immense beds of the vestiges of former testaceous animals, we may conclude, that living examples exist in countless myriads.

The mode of production is various; some of these creatures are viviparous, or bring forth their young alive, as is the case with most of those which inhabit bivalve shells, multivalves, and even some of the univalves, while others, which form by far the greater portion of such as are known, are oviparous, or produce their young from eggs. The animals constructing shells, do not, generally speaking, exhibit any known affection towards their progeny, though many possess that wisdom termed instinct, in depositing them not only in secure places, but especially where food, the first want of nature, will be amply supplied, without much trouble to obtain it. Adanson mentions that the female of the *Voluta gondola* of the Linnæan school, collects its young for some time together in the fold of its foot, and the female of the oviparous *Paludina* also carries its young some days on its shell. Species of the *Buccinum*, *Purpura*, and probably many other genera, whose eggs are pedunculated, or having a stem, are attached, at their exclusion, to the neighbouring substances. The *Janthina*, which is always found floating, surrounds its shell with eggs; the snail and others of its congeners conceal their eggs in the hollow of trees, beneath stones, in damp places protected from the sun; the *Ocythoë*, of the *Argonauta*, appears to place its eggs at the bottom of the shell it inhabits; muscles attach their young by means of their channelled foot; and *Balanis* do the same with the long tube which terminates their oviduct. Most other molluscs lay their eggs as chance directs; and it is possible, from the viscous matter that surrounds them, they are enabled to adhere to marine substances, where, at the period of their development, they find themselves the most advantageously placed according to their future wants and habits. By far the greater number of eggs produced by molluscosus animals are mucous; some are horny, and some are covered with a calcareous coating, resembling those of birds, as is the case with one or more species of *Achatina* and *Bulinus*. In one fact all naturalists agree, that whatsoever the mode of production, whether from an egg or otherwise, the shell is formed on the body of the young animal proportioned to its then bulk; the increase this shortly requires, and the consequent necessity of enlarging its shelly dwelling, we will now explain. For this purpose the common snail shall be our preceptor; its example holds good with all shells, being formed of spiral convolutions, whether they are aquatic or terrestrial. The principal use of shells is, doubtless, to cover the animal entirely when in want of such a protection, or merely

to defend certain delicate organs most subjected to injury. Some writers have considered them analogous to the bones of other animals, although its formation and growth are widely different, since it serves as a base or support to the muscles which are attached to its internal surface.

Reaumur, to whom we are indebted for numberless interesting and accurate observations of the phenomena of nature, thus describes the increase of shell which takes place after the development of the animal and its progress of growth:—"The enlargement of shells after this period is owing to successive additions of calcareous and animal matter, independent of any organised structure. When a testaceous animal is about to enlarge its shell, the common snail for instance, and its body has become too large to be covered securely, it projects a portion of its body from the opening; it then attaches itself to a wall or other solid substance, and the naked part is soon covered with the fluids which are excreted from its surface; the pellicle, or covering, which they produce, when the fluid dries, is, at first, thin and elastic, but gradually assumes more consistence, and becomes at last similar to the whole part of the shell. If, in this stage of the process, a bit of the shell is broken off and removed without injuring the body of the animal, the skin of the snail is soon covered with a fluid which gradually thickens and becomes solid. In about twenty-four hours after the operation a fine crust may be observed, which constitutes the first and external layer for repairing the breach that was made; at the end of some days this layer becomes thicker, and in ten or twelve days, under favourable circumstances, the new piece of shell has acquired the same thickness as that which was removed, but it never unites in the same way, being only as it were a plug. If, after the broken piece has been removed, particularly if the fracture is made near the edge of the opening, the animal is not supplied with a sufficient quantity of nourishment, its bulk is soon diminished, and now finding what is left of the shell equal to completely cover its lessened body, no exertion takes place for the production of a new portion. It is obvious, snails, &c., cannot enlarge in volume but by the augmentation of the whorls, and that each previous turn of the spire remains the same in length; these make a great difference in the size of the shell, by the last and additional one, each being calculated to contain nearly double that of the preceding one; but in many shells, both marine and river, the last whorls of the spire, compared with the preceding ones, greatly exceed this proportion. In some, the external opening is twelve times greater, or from eight to twelve: this depends entirely on the increase of the animal's body, and the duration of that increase. Those testaceous animals which have only a few turns in the spire of the shell are of this description; to the former belong such as have a greater number of turns; the growth of shells, being proportioned to that of the inhabitant, proceeds almost imperceptibly. In most shells this, however, is marked on the convex side with lines, more or less fine, giving the shell a fibrous appearance; these are called striae, which may be traced through the whole of the shell, in bivalves and in the longitudinal direction of those which have a spiral form; they cannot receive any addition without that progress being discovered on a minute examination. These inequalities must become visible, for the smallest addition of testaceous matter which is made,

must be attached to the old part of the shell, and consequently, must be more elevated than the former; whatever be its thickness, the increase, or rather the interruption of the growth is thus distinctly marked; and they have some degree of analogy with the different shoots of trees, checked by the cold of winter or advanced by the heat of summer, as is remarked in such shells which live on the land, or inhabit rivers in temperate regions; in these the shell is not enlarged during those seasons; it is otherwise, however, with regard to its thickness, for that is continually going on, from the constant exudation of small quantities of fluid from the animal's body; this addition is generally marked also by a fresh coloured stripe or band, darker than the present one."

That which appears certain is, that the growth of shells is extremely slow, and that their inhabitants are able to exist a very long period without food, particularly such as can screen themselves entirely from exterior circumstances, as is the case with the *Helix*. This is the more remarkable as the animal has not a stock of fat to exist upon as in some hybernating animals; that substance never existing in molluscs. Numberless instances of this could be adduced, and among others proving the tenacity of life in snails, the writer has received some of their species closely packed with marine shells from the Mauritius, which the day after their being unpacked were discovered wandering about, apparently uninjured by their confinement. Some lived ten days, but a want of proper food, or more probably an un congenial climate, then killed them. Another instance is recorded in the Philosophical Transactions, of snails having resumed their wonted habits, after having been imprisoned in a cabinet *fifteen years*; this is not, however, *vouched for* by the writer of this article.

These remarks are so easily corroborated by every day's observation, that they need not be enlarged upon, and those who are disposed to examine some of nature's interesting operations, will do well to begin with such as are not attended with philosophic cruelty; and as the formation of the snail's shell illustrates the growth of all similarly constructed habitations, a more attainable object cannot well be pointed out.

Having, as we think, explained the mode of increase adopted by the animals of a large proportion of the various genera of shells, we will now shortly describe a difference which exists in another very extensive division, called, by some naturalists, porcelain shells, on account of their smooth surfaces and high polish, resembling china-ware, in these there are two sets of colours, disposed in a parallel direction to each other. The external range of these colours is owing to a peculiarity of structure in the animals which inhabit them, different from that of other testaceous animals, and to an operation which does not take place in other shells. In these shells the colouring matter seems to be always deposited in two different ways, and at two distinct periods. In the first process, when the body of the shell is formed, the colouring matter is excreted from the glands in the body of the animal, and it is arranged according to the disposition of those glands. At this period the shell is only of a very moderate thickness, much less than it afterwards acquires when completely formed. On the external surface of the shell thus formed, another layer is deposited, which is more compact than the former, in some places thicker than in others, and usually variegated with different colours; the external shell

being thus completely covered with the second layer the original colours are concealed, and if the same shell were examined at the different periods of its growth or increase, it would appear like two distinct species. In the genus *Cypræa* (common cowry), this is strikingly visible; the young shell is thin; the spire formed by its convolutions very distinctly marked, and the toothed, or grooved aperture, not at all indicated: in this stage it closely resembles some species of cones, and by early writers on conchology has been so classed. As the external deposition of matter continues, the thickness of the shell increases, the spire becomes less and less, till it is altogether obliterated, and an indentation is formed on the part it occupied, by the repeated coverings it has received; the matter also undergoes a change of quality; becomes more glassy or transparent, for it is to be remarked, that when a shell has attained the largest growth it is susceptible of, the skin of the animal appears to produce a greater quantity of calcareous, and less of the gelatinous matter; the atoms composing it are no longer in regular layers or leafy, they have become extremely compressed and heaped together, their structure vitreous, and assuming a

Young Shell.

Adult Shell.

CYPRÆA EXANTHEMA,

brilliant polish, from the continual friction of the parts of the mantle, as they pass constantly over the surface of the shell during the life of the animal; this is observable in all univalve shells, most particularly so in the cowry and its congeners; each addition to the rolled form of the shell is rendered thicker, and, when it has reached its full period of maturity, the lips of the opening are become extremely thick, and with those grooves which admit certain portions of the animal's body to pass through. Thus, the different modes of increase may readily be understood, and it is plainly quite distinct, from that which we have described as taking place in the snail and similarly constructed shells, in the one, a shell may familiarly be termed built by small additions of matter to its first formation, placed as it were in lines, edge to edge, as any thin substance would be rendered wider by carefully laying a coat of varnish on its edge, adding various others in succession, as each previous one becomes hardened; while in the *porcellaneous* shells, the deposition of matter is layer upon layer, over the whole

surface of its broadest expanse, or in more scientific terms, stratum super-stratum.

The lamellar structure of shells may easily be discovered by exposing the common oysters, and such as are so constructed, to the action of heat, when the animal matter which cemented the calcareous layers is destroyed, and they are shown in a foliaceous form. The fracture of the shell is another fact illustrative of its formation; an oyster never breaks short off, but in thin scales or portions, while the snail and bivalve shells break short off in the direction of their additions to the edge of the shell, some more readily than others, according to the density of the matter composing them. In the matchless Museum of the Royal College of Surgeons, there are some beautiful preparations of shells and madrepores, in which the calcareous portion of matter has been absorbed by a chemical process, not affecting the animal matter, which remains exhibiting the precise form of the shell, by far the greater proportion of which it constituted. The chemical analysis of shells has been carefully made, and its general result proves them to be formed of a gelatinous matter hardened by a calcareous salt. The species which contain the largest portion of animal matter, appear to be those of a fibrous and pearly structure, in these exist sub-carbonate of lime and coagulated albumine. Mother-of-pearl itself is composed of sixty-six parts of the first and thirty-four of the latter. The shells of oysters contain much less animal matter, and that which does exist, more resembles a gelatinous substance; Vaqueline discovered in it sub-carbonate of lime and phosphate of lime, with sub-carbonate of magnesia and oxide of iron.

The *Patella* (limpet), which is formed of an extremely compact lamellar structure, approximates the most, in its chemical composition, those shells, which are, in general, vitreous, or, as it is termed *Porcellanic*; these contain only a small proportion of animal matter, but a very large one of sub-carbonate of lime, without any traces of phosphate or sulphate of lime. Human chemistry has brought to light many wonderful phenomena, and has gone some length in elucidating them; but great as these discoveries have been, they are no more than as distant planets in the wide-spread firmament, when compared to the operations incessantly performing in nature's laboratory. By the aid of chemistry we may, indeed, decompose nearly every substance in nature—dissolve some of them into air—collect the gases again, and prove, by the test of the most accurate weights, that no portion of the original bulk is lost, though rendered invisible to the eye; it is therefore, almost demonstrable, that the globe weighs no more at this moment than it did at its first creation, the destruction of some portions of it contributing to the formation of others, nothing being lost. But here, human science stops; we cannot take the elementary atoms and fashion them into a rude oyster or rough pebble; in this the master touch is wanted, all the accumulated wisdom of ages past, or of generations to come, can do no more, can go no farther, than to approach nearer and nearer, by slow degrees, the impenetrable barrier eternally fixed between omnipotent wisdom and finite judgment.

Another constituent portion of many shells is an external covering called the epidermis, the precise use of which does not appear satisfactorily explained; it is evidently the epidermis of the animal's skin beneath which the shelly matter has been deposited

This epidermis is formed of a dried mucus, or horny matter, forming a covering more or less thick—in some shells it is more or less united, in others thick like fur, or disposed in ridges. In bivalves this part is formed of the same substance as the ligament, and sometimes totally envelopes the valves, as in the *Mya*, *Solen*, &c. Its growth keeps pace with the increase of the shell, whether it afterwards remains upon it or not.

The opercula of shells, though not absolutely a portion of them, nevertheless belong to the animal possessing them, and which, in the modern arrangement of Malacology, must be studied with their coverings; these interesting parts have been scientifically treated by Mr. Gray, F.R.S.; they tend greatly to assist in the classification of molluscs, to point out their structure, peculiar habits, and to form an admirable guide to localities, otherwise without positive indications.

The colouring matter of shells may be said not properly to belong to them: it is always extremely superficial, and is produced by the coloured pigment secreted on the surface of some portion of the animal's body; these are coloured atoms, deposited above the calcareous matter, and are of a different nature, since they form no necessary portion of the shell's strength, disappearing under circumstances of age, injury by artificial heat, the application of acids or other causes. The colours are always more vivid in young animals, and the recent portions produced by them. Anatomists have proved, that it is only the limb or anterior edge of the animal's mantle which produces these colouring molecules, for, if a hole is made in any other part of the shell than at its edge, the reparation is made with matter quite colourless, and forms a white spot. In the snail (*Helix nemoralis*), which is so elegantly zoned with bands of black upon a yellow ground, it may easily be seen that the portion of the animal's body corresponding with these, presents a tinge of that colour, so that a fracture made there, on the extreme edge of the shell, is restored by a similarly coloured portion to that injured or removed, provided the broken part is altogether removed, otherwise, we see in the snail, inhumanly crushed to a shapeless mass, repeated proofs of the reparations made by the animal being perfectly colourless, every where but at the lip of the shell; in this state examples may occasionally be met with, so industriously mended after what was deemed a total destruction of the animal, that its shell appeared made up of numberless patches, as variously disposed as Harlequin's jacket.

Though we have no certain proof that all other shells, whose coloured zones run spirally from the summits, are similarly formed, analogous reasoning authorises us to draw that conclusion; but with species whose colouring matter is externally deposited in oval, square or irregularly formed spots, and particularly where the transverse bands, or stripes, are in the direction of the additions to the shell's growth, that is, perpendicular from the summit to the base, the analogy is not so evident; without we subscribe to the doctrine of some naturalists, that there is a change, a displacement, either regular or not, in the colouring parts of the animal's mantle, under peculiar circumstances of structure, constant and undeviating as any other of nature's laws. These phenomena admit, however, of much speculation, and can only be explained by a long series of accurate observations of the animals themselves in the different

stages of their growth, a thing so difficult to come at, and requiring a particular train of study to benefit from, when within our reach, that we must content ourselves with well-grounded supposition, in the absence of positive proof.

We have just said that the coloration of shells is constantly superficial; this, however, must be qualified when speaking of such shells as we have described under the name of porcelainic, the cowry, and some species of olive. The formation of the cowry having been explained, it is obvious that, during the animal's young state, the colouring matter is external, and proceeds from the same causes as in other shells. This coloration is due to the edges of the mantle, and is gradually made as the animal increases in size; but, probably at a later period, when it has attained its complete maturity, the cutaneous appendages on each side of the animal's body, when it climbs, are elevated on the back of the shell, depositing that vitreous or glassy ivory coating, which gradually thickens it, and at the same time leaves a colouring matter, constantly presenting a different disposition to the first. It must then be admitted, that the upper part of these cutaneous lobes possess intervals where the pigment is coloured, imbuing the cretaceous matter exhaled from them; and, as it is very unlikely, indeed almost impossible, that these spaces or intervals in the development of the lobes, should exactly cover the part on which the colour is deposited a second time, it is easily to be conceived that the markings are necessarily irregular, and can never exhibit either bands or any other running design. An examination of the leopard cowry, in its adult state, will render this subject easily understood, and in the map cowry, though a more rare shell to meet with, it is yet more strikingly illustrated; in this, the space not touched, or totally covered, by the cutaneous lobes of the animal's body, is distinctly marked by well-defined lines, distributed in various curves like the face of a map, from whence its appropriate name. This is visible in the common and other cowries, but not so strongly marked.

We must also remark, that the colouring matter of some shells is occasionally on the *internal* surface, of bivalves in particular. In these exceptions to the general rule, the effect may be attributed, we think, to the matter deposited, and it appears to be produced by an impregnation of colour, gradually extending in depth as well as surface, occasioned probably by some humour of the animal's body, produced in any organ, the immediate contact of which with the shell, tinges it of the colour of that secreted fluid. This appears to apply to the yellow and brown interior of some univalve shells, which certainly is caused by the liver of the animal being in contact with them; the *Janthina* is also coloured by similar causes. It may, however, be generally asserted, that it is extremely rare to find the component strata of shells otherwise than white; they are, however, sometimes, as has been stated, both externally and internally, tinged with colouring matter.

We said that light and heat exercise a prodigious influence in the colouration of shells, as well as it does in the other portions of creation. All such as are inclosed in the interior of the animal, in holes of wood, chalk, or in other situations from whence they never emerge, are constantly white; but another more striking example may be adduced from certain bivalve shells, which being fixed more or less hori-

mentally, even where one valve is not attached to any substance permanently, the lower side is always colourless; the *Spondylus*, many *Pectens*, and some other genera, fully illustrate this fact. Shells inclosed in sponge, or other foreign bodies, are invariably colourless. It must, therefore, be admitted that one lobe of the animal's mantle not receiving the exciting action of light, produces no colouring pigment, and the contrary with regard to the other; or perhaps the pigment itself only becomes coloured by the action of light on the fluids of the animal's circulation, so that if the shells were removed from the place of their habitation, and their position reversed, there would be a consequent change in the coloration of their valves, which is exhibited in some species of the *Pleuconecta*. It may generally be remarked, that those shells the most exposed to the action of light and heat, are invariably the most brilliantly coloured. The *Helices*, which are terrestrial animals, in fact, vary the most in colour, and have them of the most vivid tints; but when they inhabit the umbrageous shades of the forest, they become paler, and less distinctly marked, than the same species living in open situations; the coloured portions of the shell itself are more intense than those partially concealed of the same hue.

Almost every colour of the rainbow is to be met with in shells, varying in their degree of intensity; the most common, however, are the brown and fawn; green is incomparably the most rare, the peculiar markings of these colours depending upon the anatomical structure of the animal secreting them, cannot so clearly be understood as we could wish; indeed, the causes are as yet very incompletely known, but they are infinite in their combinations and variety, and baffle the skill of man to imitate. What can exceed the beautiful pencilling of the *Cones* and *Volutes*, or the vivid hue of their colours, and those of many other genera too numerous to be here named.

It being understood that shells are the protecting coverings of the animals forming and inhabiting them, that they are of various forms, corresponding with the naked body of the animal; more or less thick, the fracture either short or lamellar, and constantly attached to the body of the animal; we shall now proceed to explain some of the technical considerations connected with the study of the science of *Testaceology*, without any reference to its enlarged view, which will be entered upon under *Malacology*. In the first place, considering these bodies in a general point of view with regard to their structure, the first divisions of shells may be considered between those that are called *true* or *false*. A false shell (*pseudotesta*) is that not belonging to a molluscous animal, or rather a shell composed of small polygons, placed side by side, the whole forming a hard, brittle, calcareous envelop, as in the *Echini*. A true shell is that which is formed by laminae or strata, each one placed beneath the previous one, the most recent and considerable being the last internally deposited, the smallest in substance and the oldest in formation being the external; this applies to every species of shell, whatever may be its form, or the number of pieces composing it. A general study of that form occasions another division between such as are tubular or not, but little explanation is necessary to point these out, as every one will easily recognise them from such as are spirally formed. The nontubular shells are divided into such as consist of one piece—these are the *univalves*;

the *sub-bivalves* are those consisting of a principal and an accessory part; *bivalves* are all those consisting of no more than two pieces; *tubivalves* are such shells as have two principal pieces, with an accessory one; and the *multivalves* are such as have a greater number of portions or pieces. A valve is therefore a calcareous portion of shell, varying greatly in point of form, either concealed within the animal's skin, or protecting a greater or smaller portion of the animal's body. Multivalve shells are of three descriptions; those that are composed of transverse pieces, as in the *Chiton*; those that are formed of five valves, or more, symmetrically arranged to the right or to the left hand, sometimes placed in the form of scales united together by means of the animal's skin; these form a division established by De Montfort, under the title of *dissivalves*, as occurs in the genus *Anatifera*; and, lastly, those shells in which the pieces or valves are placed in a circular manner, as in the genus *Balanus* and its congeners, which form Lamarck's *sub-coronals*. Tubivalve shells are those composed of two principal valves, as in bivalves, properly so called, but surrounded or enveloped by another piece in the form of a tube, which, nevertheless, cannot be considered as another valve; this is observed in the genera *Teredo*, *Pistulana*, &c. Bivalve shells are such as their name indicates, formed of two pieces, these two pieces notwithstanding being only one cover or dwelling for the animal inhabiting it; they are nearly in every instance placed on the sides of the animal, and connected with each other, inasmuch as the functions of the animal are double, and those which apply to one valve apply equally to the other. Where the valves are not entirely similar in their configuration much error has been occasioned; and Linnæus considered the *Lingula* an univalve, having seen only one valve, in the genera *Orbicula*, *Chama*, and some others; the dissimilarity of the valves, were they not well known to naturalists, might lead to similar false conclusions. Sub-bivalve shells are those in which, besides a piece analogous to that which constitutes the univalve shells, there is a second more or less perfect—calcareous or otherwise, closing more or less completely the aperture of the shell, which piece is called the operculum.

Univalve shells merely present one constituted piece, no matter what its form, or how differently it may be modified in the different species; it altogether forms an asylum for the animal in cases of repose or danger, or, as we have already stated, protects such organs of delicate sensibility as are the most exposed to accident. An univalve shell may be completely tubular, or entirely concealed in the animal's skin. Having drawn these distinctions, we will proceed to examine each of these species of shells, commencing with the most simple, and going on to the most complicated structure; but, in the first instance, we will define the terms derived from the analogous habits of each, which consequently apply equally to univalves as well as to bivalves. Shells, no matter what number of pieces compose them, must be considered as alike in various circumstances common to all, which we will rapidly examine. From the situation in which Molluscs are found, they have been distinguished into terrestrial; fluviatile, or those inhabiting fresh water; and marine, or those dwelling in salt water.

Terrestrial are such as are found on land, and are so organised as not to be able to exist in a fluid; they breathe air only.

Such only are known in the division of univalves and sub-bivalves, as it is quite impossible that bivalves or multivalves, which are tenanted by aquatic animals, breathing water, should be found on land.

Terrestrial shells are generally very thin; their exterior surface usually smooth, presenting no other inequalities than the striæ, indicating the different stages of growth, sometimes with piliform prolongations of the epidermis, but never with spines, or other protuberances properly so called; their internal or external surface is never pearly; their aperture is always entire, particularly in the adult state, with the right side of the lip thickened into a ridge more or less turned outwards.

Fluviatile shells comprehend all those that live in fresh water, whether stagnant or current; some of them are found in the three first divisions of shells, viz. the univalves, sub-bivalves, and bivalves, but none are yet known in the multivalves; the number of fluviatile shells is considerable compared with the others, and is confined to a very few families. So amongst univalves, the greater number known have the aperture entire, either operculated or not, but above all in the last group. One or two genera, at the most, have it grooved, though very slightly, as in the *Melanopsis*, and there is perhaps only one genus in which it is patelliform, like a *Limpet*. The bivalves of this section only belong to three or four families; the only ones known are those of the *Mytilus*, *Submytilus*, *Chama*, &c., and even then it is often a single genus, or a solitary species. Fresh water univalves and sub-bivalves are in general thin, since they belong to swimming animals; their external surface in general finely striated, without bands or varices, but sometimes with spines; and when there is an epidermis, it is always very thin. One of their general characters is that of having their aperture entire, but the *Melanopsis* forms an exception to the rule, not only in that respect, but as being often of a considerable thickness: thus the distinction between fresh water univalves and sub-bivalves is less easy than in the terrestrial. Fluviatile bivalves are nearly in the same case; it has, nevertheless, been remarked, that whether the substance be thick or thin, they have nearly always a rather thick epidermis, the valves shut completely, they are more or less pearly within, and the summits decorticated in most species.

Marine shells may be said to exist of all families, except those of the snail, and other of their congeners, and of the first section of the *Submytilus* among the bivalves. Their characters are opposed to those of the two first sections. Thus the univalves, and even the sub-bivalves, are in general much thicker, and more frequently marked with ridges, varices, and spines. Their aperture also differs from the preceding, by being very frequently channelled, and bordered on the right side by a simple or complex ridge. They are sometimes pearly on the inside; the epidermis is often scaly, piliform, and, generally speaking, totally different from either the fluviatile or terrestrial species. Marine bivalves are in general more rough on their exterior, with more strongly defined striæ, grooves, and rays; their epidermis is less smooth, even thinner, and usually of a very different form from that of the fluviatile shells. With regard to the parts of rivers, lakes, and seas, in which molluscous animals live, they are sub-divided into littoral and pelagic shells; the littoral are those, either univalves, sub-bivalves, bivalves, or multivalves, which inhabit

more or less constantly the sides or banks of rivers, lakes and seas; the pelagic are, on the contrary, those molluscs always inhabiting the deepest parts of the sea, in consequence of which they are the most difficult to come at, and but generally only known through accidental circumstances. There is not, however, any permanent distinguishing character for these shells, so as to enable the naturalist to decide, by an examination of the shell only, to what habitat it belongs. A moderate degree of experience will, nevertheless, give certain rules going far to establish the fact, without any knowledge of the animal. There is not, either, any indications on the shells themselves to point out such of them as are found embedded (in some instances it is difficult to say how) in wood, stone, &c. As a general definition, these are called (*Terebrantes*) borers or piercers, and distinguished from each other, as *Petricola*, or *Lithodoma*, when found in calcareous substances, of a more or less hard texture, as with the *Pholodes*, &c.; *Xylocoma*, or *Lignivora*, when they have established their habitations in wood, as is the case with the *Teredo*; *Arenicola*, when they inhabit the sand; *Lutricola*, when buried in the mud of rivers, ponds, &c. An observation may, however, be here made with respect to such of the penetrating molluscs which inhabit hard bodies. They are only to be met with in some families of bivalves, and a tolerably uniform indication may be discovered in the larger and more rounded form of their anterior extremity. It is also pretty easy to distinguish, by certain marks, such molluscs as are more or less fixed in their local habits. These shells may be divided, in consequence, into those being (*Natantes*) floating, that is, inhabited by swimming animals. They are then wisely constructed of a very thin light substance, which is beautifully exemplified in the *Argonauta*, *Janthina*, *Bulla*, and others.

The *Liberæ*, or free shells, are such as are more solidly constructed, and presenting no sign of adherence, or power of attaching themselves to submarine or other bodies. This is the case with the greater proportion of shells.

*Adhærentes*, or adhering, when they are altogether immovable, or only possessing the power of moving in a very limited space. To the extent of their attachment, these are denominated

*Fixæ*, or fixed, when their attachment is by means of the adhesion of the substance of the shell itself, as is the case in univalves with the

*Hipponix*; in the bivalves with the *Spondylus*, *Oyster*, *Chamae*; and in the *Balani* among the multivalves.

*Radicatæ*, rooted, when the adhesion is effected by means of a tendinous part, as is the case with the *Terebratula* and *Lingula* in bivalve shells; the *Anatife* in multivalves. This Linnæus improperly designated *intestinum*, an error perpetuated by Brugniere, who translates it *intestine*. This adhering portion is often marked in the shell, but it is sometimes indicated by a hole or groove in one of the valves; and lastly, molluscs are called *Obtectæ*, or hidden, when they are concealed at a certain depth in a distinct tube, to which they adhere, or remain loose, enveloping the animal altogether, as in the genus *Fistulana* and its congeners. We will here describe the position of the shell as viewed by modern naturalists, in describing the various names ascribed to its different parts. In this a well-marked and

extremely rational change has taken place since the revision of the Linnæan school; and it is now the more useful, as it tends to facilitate naturally the connection we deem inseparable of the animal and its dwelling, which forms the leading feature of the science of Malacology. Our present object is, however, confined, as we have already premised, to the shells themselves, as detached portions; and before we proceed to the nomenclature of the science, the following easy guide should be well retained in the student's memory. It will be the more readily understood by an examination of the accompanying descriptive figure; or we may at any time observe the march of our garden snail as a living guide to the subject. In univalve shells, it is easily conceived that they must have had a point or portion from whence they progressed in growth, a base which is its actual termination in its final stages of increase, or in its adult state of maturity, with an intermediate state between these, which may be called the body of the shell. This portion sometimes possesses an almost imperceptible cavity in such as are extremely depressed, or altogether flat, in which they partake greatly of the character of one valve of a bivalve mollusc.

PLEUROTOMA BADYLIONICA—*a*, the canal; *b*, the nearly closed umbilicus; *c*, the left or intestinal edge or lip; *d*, the right or external lip; *e*, the notch or slit; *f*, the sinus; *g*, the belly; *h*, the turns or whorls of the spire; *i*, the sutures.

Linnaeus, of the old, and Lamarck, of the modern school, placed the shell they were about to describe on the opposite extremity to the summit, its only natural position when separated from the animal, but with the aperture fronting the spectator. Modern naturalists, on the contrary, place the shell as it is found on the animal when proceeding on its march, that is, with the spire towards the observer, the summit consequently upwards and behind, and the opposite portion, or the base, as it is generally called,

in front and beneath. In this mode of examining a shell, it is clear that the right and left side apply equally; but the one so called by Linnaeus is now, by reversing the position of the shell, exactly the contrary of modern authors. The right of the old system is the left of the modern, and *vice versa*. The terms, *inferior* and *superior*, in the description of the aperture and its edges, are necessarily replaced by the terms, *anterior* for the first, and *posterior* for the second. The *upper*, or summit, is that part from whence the shell first proceeds, or, more properly, it is the commencement of the spire. This portion may be altogether flat, or very salient, straight or vertical, or directly leaning backward, to the right or to the left, or even forward. It may be pointed, mamillated, entire or carious, and even sometimes hollow, as in the *Bulla*. Thus the summit is altogether *planus*, or flat, as in the Chinese limpet; *peracutus*, or very salient, as in the *Vermetus*; *verticalis* or vertical, as in the *Patella* or limpet, whence Linnaeus has called it (*vertex*;) *marginalis*, and *sub-marginalis*, as in the *Crepidula*; *retroversus*, depressed backward, as in the *Navicella*; *anteverus*, the converse to the latter position, as in certain species of *Patella*, and, above all, in the *Emarginula*; *sinistralis*, or left-handed, as in the *Ancylus*; *dextralis*, as in the *Capulus*; *acutus*, pointed, as in a great number of shells; *mamillaris*, mamillated, or rounded, as in the *Volutes*; *integer*, or entire, as in the greater portion of shells; *cariosus*, eroded, or carious, as in the *Bulinus thiana*; *truncatus*, or *decollatus*, as in the truncated *Bulinus*, and several other species of turriculated molluscs; *umbilicatus*, umbilicated, hollowed, sunk in, as with the *Bulla* and their congeners, as also with certain species of *Ammonites* and *Planorbis*, but then the apex is lateral; *terebtratus*, pierced, as in the *Dentalium*. *Basis*, or the base of a shell, is that part which is usually opposed to the summit, and in which the aperture is formed. Under this name, however, we do not understand that which Linnaeus and his disciples have designated as the base of a shell; for in fact, according to their view, it is the extremity, pointed or not, which is opposite to the summit, and they made it so, because, according to their method of designating the different parts of shells, they placed this one vertically, the summit above and the aperture behind. In the present school, the base comprehends all that part which rests more or less obliquely on the back of the animal. Sometimes this base is very large and round, *ampla, rotunda*, as in the *Trochus*, which gives them the form of a reversed one; sometimes it is *parva*, small, as in the *Terebra*, *Subula*, &c. It may be extremely elongated, *elongata*, as in the *Cypræa*, &c.; and it is formed entirely by the aperture, as in the *Patella sigaretus*; but many other molluscs more frequently have their base formed by a portion of the last turn of the spire.

The direction of the base, which is usually in that of the opening, also offers some considerations deserving notice; it is altogether perpendicular to the imaginary axis of the shell in the *Patella*, *Solarium*, &c.; it is almost entirely in that of the aperture in the *Oliva*, *Cypræa*, &c.; in other shells, it is more or less intermediate.

That portion of shells termed the body occupies the whole space between the summit and the base. It is most frequently hollow, and not only serves as a covering, but also contains the whole, or a part of the animal's body.

Sometimes the name of disc (*discus*) is given to the base of shells, as in the *Haliotidea*, but it is then only the last turn of the spire which is comprehended under that name.

In a certain number of shells, the body part is not inclined in any direction, either to the left or right, forward or backward, and it is not at all excavated; the shell is then truly a flat shell, symmetrical in the *Sepia*, &c., and not symmetrical as in *Patella Smensis*. It frequently occurs that the base and the summit are united by a portion not curved in any direction, but more or less excavated. These we have already designated as shells covering the body of the animal altogether. This occurs in the *Patella*, *Emarginula*, and particularly in the *Dentalium*; most frequently, however, the body of the shell is formed by its convolutions in their various directions, whence they are properly called spirivalve (*spirivalvæ*). To illustrate this familiarly, suppose all univalve shells to be of a conical form, more or less elongated, the *Dentalium*, for instance, and imagine it flexible; if this be rolled up, or curved from the posterior part forward, and from the top to the bottom, positively in the same vertical plane, the result would be a discoid shell, compressed from the right to the left, the summit of which can only be visible in the same direction, and the axis of which is everywhere equally transversal. Such shells may be called rolled up (*revolutæ*). An example strictly in point may be found in the *Argonauta* and its congeners; but the *Planorbis*, though in some respects analogous, are in fact only *sub-revolutæ*.

The principal distinctions, and the various modes in which shells are rolled, consist in their greater or less degree of perfection. They are called arched (*arcuata*) when the shell presents only a slight curve, as in certain species of *Belemnite*, and as in the *Dentalium*. Curved (*curvata*), as in the *Ammonoceras*, the shell presenting a much more circular curve.

Half-coiled (*semi-revoluta*), when the shell is so curved as that the turns of the spire do not touch, which occurs in the *Spirula*, presenting a spiral coil on a plane.

Coiled (*revoluta*), when the turns touch each other, as is the case with the true *Ammonites* (*per-revolutæ*), when the spiral turns penetrate each other in such a way that the last conceals all the others; which is illustrated by the *Nautilus*.

If, on the contrary, the revolutions of the spiral cone are formed transversely from left to right, as placed on the animal, such shells are termed involuted (*involutæ*), or, as Linnæus calls them, *convolute*, convoluted. In these species the base is nearly the whole length of the shell, as well as the aperture, and the axis of revolution is necessarily longitudinal. In fact, shells are scarcely ever completely involuted. Those which the nearest approximate that form are the *Ovula* and *Cyprea*. Sometimes the shell does not form a complete turn, as in the *Bulla*, and then the aperture is as large and as long as the shell itself.

The greater proportion of univalve shells are, however, intermediate with the two above-described formations; that is to say, the body of the shell is the result of an oblique revolution from right to left, and from the lower to the upper part, if we proceed from the bottom to the top; or, on the contrary, which is more natural, if we view the shell according to its progress of growth. Such are the true spiri-valve, or turbinated shells.

The name of spire (*clavicula*) is given to all that portion of the shell which is formed by the revolution of the spiral cone. Sometimes the last turn of the spire, which is usually the largest, is distinguished by the name of body (*corpus*); the part corresponding with the aperture is the belly (*venter*); that which is opposed to it is the back (*dorsum*); to all the other parts of the shell the term *clavicula* applies. By far the greater number of molluscs terminate on the right side of the animal; some, however, which we have pointed out, terminate to the left; and this circumstance distinguishes the sinister from the dextral shells, *dextræ* and *sinistrorsæ*.

Having thus pointed out some of the leading distinctions which characterise the plan of formation presented by shells, we shall briefly enumerate the scientific terms applied to the position of the shell with regard to its inhabitant, leaving the general nomenclature to an alphabetical arrangement.

Dorsal (*dorsalis*) shells are such as are placed on the back of the animal. Of these there are only examples to be met with in the univalves and sub-bivalves; and in the *Chiton* among the multivalves.

Ventral (*ventralis*) applies to shells placed beneath the animal's belly. The genus *Ombrella* may be supposed so situated.

Dorso-ventral (*dorso-ventralis*) are shells composed of two pieces, the one on the back, the other beneath the belly, as in the *Terebratula*, *Lingula*, &c., and others of the class *Palliobranchiata*.

Bilateral (*bilateralis*) are those of which the component parts are, one on the right, and the other on the left of the animal, as in the *Ostrea* and its congeners, which occurs in all the class of the *Lamelli-branchiata*.

Perisomatic (*perisomatica*), when the pieces forming the shell beyond the number of two, surround the body of the animal, as occurs in the *Balanus*, *Anatifa*, and their congeners, constituting the class *Nematopodes*.

External or internal shells have been so called from anatomical investigation of their position with regard to the animal. External is applied to nearly all shells which cover the skin of the animal, and it is so obvious, that no further explanation is requisite.

Internal shells are those in contradistinction to the generality, which are partially covered by some portion of the animal's skin, more or less thick. The shell is then, for the most part, very thin, flat, or only slightly revolved. It is constantly of a pale colour, and does not ever possess an epidermis. No examples of these are found out of the order *Polythalamacea*, or many chambered shells, as also of the single chambered, or *Monothalamacea* order. Certain species of *Mya* may also be presumed so situated as to be properly termed internal shells.

The terms applicable to the structure of shells depend upon the solidity and arrangement of matter composing them. Thus shells are called solid (*solida*) when they are heavy and capable of resisting considerable violence, such as the *Mitres* and *Olives* in univalves, and the *Spondylus*, *Crassatina*, *Pectina*, and other of the bivalves; fragile (*fragilis*), when on the contrary.

Thick (*crassa*), generally understood to apply to the valves rather than to the whole shell.

Thin, papyraceous (*tenuis*, *papyracea*), when the shell is excessively thin.

Transparent (*translucida*), when such thin shells

permit of the rays of light to pass partially through them, as is the case with the *Carinaria*, *Anatina*, &c.

Lamellar (*lamellosa*) or foliaceous (*foliacea*), when the strata of matter are not compact and solid, particularly towards the edge of the shell, as in the *Oyster*.

Fibrous (*fibrosa*), when the shell fractures in a perpendicular direction, from its summit to the base, as in the *Pinna*.

*Nuda*, or naked, as in shells whose surfaces appear highly varnished: the *Olives*, *Courres*, &c.

Corticated (*corticata*), or epidermata, when the edges (of the stria of increased growth) form on the surface of the shell, an envelope more or less thick, the appearance of which occasions their being distinguished as furry or scaly.

The chemical composition of shells separates the species into such as are sandy (*arenacea*), in which the calcareous molecules are not united with each other, so that they may easily be reduced to small portions or grains, as in the *grey snail*.

Creteaceous (*cretacea*) or chalky, when the superabundance of calcareous matter, renders the shell extremely friable, as in the *Tubicola*.

Horny or membranaceous (*membranosa*) when, on the contrary, the mucous matter constitutes nearly the whole of their substance, as in the *Aplysia*.

The colours of shells, as of everything else, does not admit of any misunderstanding, and must be applied according to the ideas each one forms of their degree of intensity. They are infinite in their combinations, though not a very important consideration, as they do not affect any peculiar arrangement; they may, be noticed under two heads. Superficial (*superficialis*) as in shells, externally coloured, as most species are; or imbued (*imbutus*) as in shells, where the colouring matter penetrates the substance, such as the *Janthina* and others.

The system of coloration, or as it is more familiarly termed, the marking of shells, gives rise to the following generally used distinctions. It is uniform (*uniformis*) when equally distributed over the whole surface of the shell; or variegated (*variegata*), on the contrary, when the colouring matter is variously arranged, and these differences of marking are called fasciated, ribboned (*fasciata*), when the zones or bands are of a different colour from the groundwork; it may be fasciated longitudinally, when they run from the summit to the base, following the direction of the whole of the spire. In bivalves this is distinguished by radiated or rayed (*radiata*); or, if in the direction of the striae, which mark the shell's growth, they are termed transverse (*transversalis*); lineated (*lineata*) when the coloured bands are closely placed, like hair lines, as in the *Bulla physa*; lettered (*scripta*), when the bands are more or less waved or broken, resembling Arabic characters, as occurs in some of the *volutes*. Tessellated (*tesselata*), when the system of colouration presents large spots, or other shaped marks, comparable to inlaid marble or mosaic work. When these markings are round, or nearly so, they are called spotted (*maculata*), and when the spots are disposed in bands, the shell is said to be ribbon-spotted (*fascio-maculata*); when the spots are very small, resembling fly-marks, they term it dotted (*punctata*), and *fascio-punctata*, when these minute dots are disposed in bands.

Of the general form of *Univalve* and *Sub-Bivalve* Shells.—In considering the general form of Univalve shells, without paying attention to the distinction of their parts, certain terms are used which, although

rather vague, must necessarily be known. The first distinction regards the equality or inequality of the two sides of a shell of any form whatever, separated by a fictitious axis drawn from the summit to the base, or from one extremity to the other. A symmetrical shell is one whose valves are perfectly equal, and a non-symmetrical shell, such as has its valves unequal, thus the shell of the *Argonauta*, the *Lippet*, &c., are symmetrical; the *Sigaretus*, and many others, are non-symmetrical.

A flat shell (*plana*), is that which has no cavity; tubular (*tubulosa*), that of which the diameter is considerably less than its length, as in the *Dentalium*; recovering (*aperiens*), that which is conical, and without a spire, properly so called, and so placed on the animal as to be easily taken off, as with the *Limpet*; spiral (*spiralis*), that which is more or less twisted in various fashions, as we shall more fully explain hereafter; but for the moment we will continue to define some terms belonging to the shell examined as a whole. It is called discoid (*discoidea*), when it resembles a disc, and which, considering the manner in which the spire is evolved, we call rolled up, as occurs in the *Ammonites*; depressed (*depressa*), such as are oval, or rounded very flat, the spire very short, as the *Sigaretus*. The same name is sometimes employed to designate certain shells whose last whorl, or the body of the shell, enlarged by lateral bands, appears flattened from the top to the bottom, as in the *Ranella*; globular (*globosa* or *ampullacea*), that in which the diameters are nearly equal, occasioned by the great development of the last whorl of the spire, which is much larger than that which preceded it, as in the *Ampullaria*, &c.; oval (*ovalis*), when the longitudinal diameter is rather longer than the transverse, as in the *Courres*, *Olives*, and many others; bordered (*marginata*), when the edges are of a greater thickness than the rest of the body, as in some species of *Cowry*, &c.; navicular (*navicularis*), some shells which, reversed on the back with the aperture upwards, have some resemblance to a little boat, as in the *Argonauta*; pyriform, when one of the extremities is inflated and rounded, and the other pointed in the form of a short tail, as in the *Pyrula*.

Claviform, club-shaped (*clavata*), when the body of the shell is short and inflated, and the anterior part narrow and lengthened, as in the *Murex haustellum* (Linnæus). Beaked (*rostrata*), when it is terminated at its two extremities by a prolongation of the form of a beak, as in the *Ovula birostris* (Lamarck). Conical (*conica*), when one of its enlarged extremities is as if it were cut square, the other being pointed and forming the summit; when it is the summit itself of the shell which forms the summit of the cone, it is then called a turbinated shell, as in the *Trochus*, and the *Turbinella*; and it is called conical or conoid, when, on the contrary, the summit of the cone is at the anterior part of the aperture, as in *Cones*, properly so called. Cylindrical (*cylindrica*), when the shell is lengthened, and nearly of the same size throughout, as occurs in most of the involuted shells, such as the *Olives*, &c. Fusiform, spindle-shaped (*fusiformis*), such as are swollen in the centre, and pointed more or less at the two extremities, as in the *Fusus*. Turriculated (*turriculata*), those that are very much elongated, that is, whose longitudinal diameter is much greater than the transverse, which depends on the manner in which the spire is formed, as in *Turritella*. After this short explanation, univalve shells may be considered with regard to the distinction of each of their parts. A con-

sideration of the different terms applied to the spire, and other parts of univalve shells, would lead into a description of terms generally used in every elementary treatise on conchology; but as it would occupy a larger space than can be devoted to the subject in a work of this kind, we will proceed to point out some of the leading characteristics of bivalve shells, as we have already done with the univalves. And here, as with them, we will first of all point out the established position from which the relative terms are taken, which is here figured.

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 1. *a, b*, length of the shell; *c, d*, height; *e*, lunula, above which is the summit; *d*, the ventral or inferior edge.

Fig. 2. The line across marks the thickness of bivalves.

Fig. 3. *a*, anterior extremity; *b*, posterior; *c, d, e, f*, muscular impressions; *g*, lower edge of the left valve.

Viewing, therefore, a bivalve shell, composed as it were of one piece, we shall explain that which is understood by long, elongated, cylindrical, transverse, thick, compressed, or very thin. We have already assumed as a point from which we shall invariably depart, that we suppose the shell covering the animal and walking away from the observer (although in fact many of these molluscous animals do not move from the place in which they were born); some others, it is true, assume positions in which the head even is downwards, when the shell would be placed on its edge, in such a way that the summits would be nearly always upwards, and very rarely forward, with the ligament between the summit and the observer. In this position the part opposed to the summits will be inferior, and the two extremities of the diameter perpendicular to this direction, will be one anterior and the other posterior. Linnaeus, Brugnière, Lamarck, Bosc, and many other naturalists, have described shells alto-

gether imagined in an opposite position, that is to say, resting on their summits, the aperture upwards, and the ligament forward. According to this position, the height of a shell will be taken from the vertical diameter extending from the summits, or from the ligament to the inferior or abdominal edge, supposed to touch the place on which the shell rests; that is the length with Linnaeus and others. The thickness, (*crassitudo*), will be indicated by the transverse diameter of the most inflated part of the two valves whence the right valve will really be that which corresponds with the right side of the animal, and the same with the left. We should then name the back of the shell, or the superior margin, that which in fact corresponds with the back of the animal in which ordinarily the summit is placed, but still more frequently the ligament. The opposite side will be the abdominal side, or inferior margin, that is its real base. In this light Cuvier and others have viewed the position of bivalves, but it is the reverse with Linnaeus, Lamarck, and many other naturalists.

The circumference of the shell, or the line which unites the four points just mentioned, forms the margins of the shell; in this position it would be easy to understand what is meant by a long bivalve, &c. It is long (*longa*) when the horizontal diameter is much greater than the vertical, as in the *Pholas*, *Mya*, &c.; it is a transverse shell of the Linnæan school. Height (*alta*), in a contrary sense, as in the *Vulsella*. Oval (*ovalis*), when one of the diameters is but a little longer than the other, as in the *Venus*. Round (*rotundata*), when the two diameters are nearly equal, as in the *Pecten*. Thick (*crassa*), when the transverse diameter is as great as the others, upon which depends the depth of the valves, as in the *Cardium*. Compressed, thin, very thin (*compressa*), when this diameter is more or less small in proportion to the others, as in the *Tellina*. Cylindrical (*cylindrica*), when the longitudinal diameter being very great, the two others are nearly equal, as in some species of the *Solen*. Navicular (*navicularis*), when the diameter, antero-posterior, being evidently much larger than the two others, the latter are nearly equal, which gives the shell a fancied resemblance to the hull of a ship, particularly when the dorsal margin is straight, as in the *Arca*. Cordiform, heart-shaped, (*cordiformis*), when seen from behind, in front, or at the side, it offers some resemblance to the received form of a heart, as in the *Isocardia*, &c. Triangular (*triquetra*), when the shell is as if truncated at its anterior extremity, but much more frequently at its posterior, so that a horizontal section, made of the whole shell, would form a triangle, this is illustrated in the *Trigonia*, *Donax*, &c. Tongue-shaped (*linguiformis*), when it resembles the form of a tongue, as in the *Vulsella*. Rostrated, beaked (*rostrata*), when the posterior extremity is much narrower than the anterior, as in several species of *Tellina*. Truncated (*truncata*), when it is, positively, as if one of its extremities were cut off, as in several species of *Donax*. Eared (*auriculata*), when the margins of the shell, towards the summit, are more or less dilated into certain portions, termed ears. Inauriculated, when only one of these appendages occurs. These ears are equal, or unequal, when of the same size, or differing from each other in size; they are spiny, when their inferior margin appears toothed; obliterated, when they are but slightly angular, as in the *Lima*.

The valves may be regular or irregular; they are regular when they present an uniform shape, totally independent of all exterior bodies, as is the case with

most bivalve shells; on the contrary, the valves are irregular when they assume the shape of the substance to which they adhere, such as the oysters—*Anomia*, &c. This occurs with both valves in some instances, as the form of the upper is necessarily modified by that of the lower valve: whether the valves are thick or thin, is so obvious, that no particular term is necessary. The valves are plaited (*inflexa*), when they form an angle or fold projecting at their inferior part, as in the *Tellens*. Each valve, regular or otherwise, may really be compared to an univalve shell, in general very flat and covering the animal, but instead of being placed on the back of the animal is situated at its sides; there must, therefore, exist a summit and a base, an external convex, and a concave internal surface. The summit of a bivalve shell is termed the beak, or tip (*apex*), and it is from that point the growth of the shell commences. Considering its general position, always bearing in mind the animal which it covers, it is oral or buccal (*oralis*), when it is at the anterior extremity of the valve, which is rarely the case; an example, however, is exhibited in the spondylus, oyster, &c., and this is commonly called the spur or heel. It is dorsal (*dorsalis*), when it corresponds with the back of the animal or the superior margin of the shell, which is ordinarily the case with shells in general; in this case it may be *antero-dorsal*, when placed more forward than backward in the length of the valve; *medio-dorsal*, when in the middle; and *postero-dorsal*, when more backward than forward; anal or posterior when situated at the opposite extremity to the mouth, as in the *Terebratula*, *Lingula*, &c.

It is also from the relative position of the summit of the bivalve shells, that the characters are indicated by equilateral, sub-equilateral, or in-equilateral. A valve is said to be equilateral when the cephalic summit is exactly in the middle of the side on which it is placed, so that a perpendicular line drawn through would sub-divide it in equal portions, as is seen in the *Pectens*. Sub-equilateral, when there is only a slight difference in its position, either backward or forward. In-equilateral, when the difference between the two sides is more considerable, and consequently the summit becomes either antero-dorsal or postero-dorsal. The direction of the summit offers also some characters designated by particular terms; it is the most frequently a little curved or inclined forward, but it is also sometimes entirely vertical, or in the direction of the diameter of which it forms one extremity, and it is more rarely inclined backward; and in some species the summit has a tendency to assume a spiral form, as in univalves. It is variously named in scientific terms according to its being—ear-shaped, spiral, recurved, entire, callous, &c., for which, as before, we refer to the treatises on this subject. The external face of the valves offers several characters important to know, it is either convex or flat, which needs no explanation, it is full (*plena*), as in the *Tridacna*; bordered (*marginata*), when furnished with a projecting rim; toothed or serrated (*dentata*), when the circumference is furnished with what may be here termed teeth, as in the *tridacna*, cordiform, crescent-shaped, lanceolate, oval, oblong, superficial, &c., according to its resemblance to a heart, as in some of the species of *Venus*, &c. The internal surface of the valves presents also many characters deserving attentive consideration, but not easily described without illustrations, that would here occupy too great a space. The valves are right hand or left, according to the position of the animal as we

have already placed it; they are equivalve, when exactly corresponding in size, depth, and general form, as exists in most of the bivalves; sub-equivalve, when the difference between the two valves is not very considerable, as in certain species of *Pectens*; in-equivalve, when there is a very visible difference, either in the form, size, or other particulars. Linnæus has named the smallest and flattest valve the operculated one, as in the *Gryphææ*; but, for the reasons we have stated, it is mis-applied. The valves of bivalve shells, placed in opposition to each other, often touch at every point of their circumference, in which case they are termed closed (*clausa*), when not thus everywhere united, they are said to gape (*hians*). In the first instance, the closing of the valves may be simple by approximation, or they may be shut by the insertion of the opposite notches, grooves, teeth, &c., with which many are furnished. In bivalves having a partial opening in the circumference of the valves, more or less considerable, it is, for the most part, only posterior, or both anterior and posterior to a certain extent, as in the *Solens*, the *Pholas*, and many other species; sometimes it is inferior, and more or less anterior or medial, as in the *Arks*, *Muscles*, &c., and it is sometimes anterior, and superior, as in the young examples of the *Tridacna*. Another point of view, perhaps more important than most of those which we have described, is the peculiar mode in which the valves of shells are united to each other; these are three in number, one belongs exclusively to the animal, depending upon the use of certain muscles or bundles of muscular and elastic fibres, which are carried transversely from one valve to the other; these leave an impression on the internal surface of the valve, the study of which has been pointed out as important in deciding the genus of a mollusc, without any previous knowledge of the animal. The second mode of union also belongs properly to the animal alone, and although much less than the first, it leaves also its indices, or traces, very perceptible in the excavations of different forms in which it is attached, this is named the ligament (*ligamentum*); it consists of a mass, more or less considerable, of horny fibres, elastic, and covered with an epidermis, carried from side to side of the valves. Some bivalve shells are met with entirely without a ligament, properly so called, as in the *Orbicula*, *Pholas*, and others, in which it is not distinct from the general epidermis, as in the *Pinna*, but most frequently bivalves possess a ligament; this is simple (*simplex*) when there is only one, as in the *Venus*; and the greater number of bivalves, double (*duplex*), when there are two ligamental processes, the one posterior, as in certain *Tellens*, whence they are called amphidesma, or when there exists one external, the other internal, as in the *Mactra*. Multiple (*multiplex*), when there is a series more or less considerable, as in the *Perna*, and, perhaps, even in an inverse position, in the *Arks*. The position of the ligament, with regard to the summits, is thus defined: anterior, when placed in front of them as in the *Donax*; medial, when immediately beneath the apices; posterior, which is the most usual, when behind the summit; antero-posterior, when both backward and forward, occupying an extended space, as in the *Arks* and their congeners. The position of the ligament, as it is externally visible or not, distinguishes it into external (*externum*), when visible, which occurs with most bivalves; deep (*profundum*), when it is so deeply placed, that it is scarcely perceptible on the outside;

as in the *Venus*, zig-zag; internal, when it is positively altogether concealed, as in the *Mactra*, *Crassatella*, and to a certain extent in the oyster. As to its being flat, round, short, long, &c., it speaks for itself.

The last mode of connexion between the valves of shells is called the hinge (*cardo*), which may be defined as a particular arrangement of differently formed prominences, or cavities on each valve corresponding reciprocally with each other. Authors call that the thickest portion of the circumference of the valve in which most frequently these cavities or teeth are situated; this is the cardinal margin (*margo cardinalis*); the cardinal blade or ridge (*dissepimentum cardinalis*) is that portion of the edge which exhibits the teeth. Examining shells with regard to this arrangement, they are called toothless (*acardis*) when no trace exists of cavities, projections, or ligament, but of these, perhaps, only one example can be offered, it is the *Lingula*. When there is only one protuberance on the part termed the hinge, more or less elongated and irregular, it is called callus (*callosa*). When the cardinal ledge, instead of being vertically placed, as is in most instances the case, is horizontally enlarged by a projection fitting into a corresponding cavity, placed beneath the summit of the other valve, or under a similar projection, Linnæus called it *dens vacuus* or *depressus*; but erroneously, not being a true tooth, and only serving for the insertion of the ligament. In all other shells provided with a true hinge, it is necessary to observe if it is exactly similar on each valve, in the first instance, it is termed therefore similar (*similis*), and in the second dissimilar. The position of the hinge, generally considered, also requires some particular denominations, which are nearly the same as applied to the summits; oval, dorsal, anal, &c., as they may be situated on the back, posterior, anterior, &c. In the different portions of the hinge it is formed complete by means of eminences and cavities, the one called teeth, the other indentations (*fossula*); when the hinge is formed by one tooth or protuberant portion, as in the *Mya*, it is called the *Sinus* by Linnæus. These eminences or corresponding cavities with relation to the summit may generally be denominated in the same manner as the entire hinge. The cardinal teeth (*dentes cardinales*) are those placed immediately beneath the summits, and are usually the principal ones. The lateral teeth (*dentes laterales*) are, on the contrary, those of less importance, and more or less separated either before or behind the summit; those placed nearest to the lamella are called *dens anticus*; and the *dens posticus* are those on the side of the ligament or shield, thus reversing the Linnæan position. The direction in which these teeth are placed distinguishes them into vertical, oblique, longitudinal, divergent, or convergent. In the *Cyrena* they are nearly vertical, oblique in the *Venus*, longitudinal in the *Cardita*, divergent or convergent, according to the point of view taken from the summit, as in the *Mactra*. The mode of junction of these teeth establishes the terms inserted (*intrusus*), which is where one penetrates between two others. Alternate (*alternus*), that which crosses another obliquely, as in the *Cardium*; articulated (*insertus*), when the hinge formed by them is produced from a reciprocal arrangement inverse on each valve, as exists in the greater number of bivalves. The particular form of the teeth is expressed by lamellar (*lamellosa*) or longitudinal when they are very long; and much compressed if short or thick; when on the contrary, straight

or curved, simple or bifid, smooth or striated, according to circumstances, too obvious to need further explanation. The number of teeth is sometimes important to observe, though they are not always uniform in the same species of molluscs. In multivalve shells, according to the modern system of classification, such as were included by Linnæus from being more or less complete tubes, which might accompany or even entirely envelope the two valves of a bivalve mollusc, were by him sometimes called accessory pieces, have been excluded, and only those completely visible are so called. Multivalve shells are constantly produced by animals which may be called intermediate between the mollusca and the entomozoria, while those of the *Pholas*, *Teredo*, &c., are true malacozoaria.

They are also very few in number, and it is scarcely necessary to dwell particularly on the denominations of their parts, as the greater portion of them are the same as those of bivalve shells; they may be called with regard to the position of their parts or valves, articulated, lateral, ante or post lateral, dorsal or ventral, but one group established by Lamarck, under the name of coronal or sub-coronal molluscs, requires a more particular notice. In these the portions constituting the shell being disposed regularly round a common axis, are firmly knit together by their margins, so as to form a complete cavity or space in the centre, closed or open inferiorly, and shut superiorly, by a small number of pieces of various forms, the total of which is called their operculum, or lid; the form and number of principal pieces, as well as those thus termed the operculum, varies so much that they merit distinct terms to designate them. The support (*basis*) is always monotonous, and may be simply membranous, irregular, or patelliform, in which case it may easily be confounded with the *Limpet*. The terminal or operculated portion is at least ditomous, because it is always in pairs and symmetrical, but then each lateral piece is most frequently divided into two valves, the one dorsal, the other ventral, according as they correspond to the analogous coronal pieces. This operculum is called articulated, when it evidently touches the coronal portion; it is inarticulated when entirely surrounded by the membranous portion of the aperture. The principal portions of these shells have occasioned their being called coronal, because they form a sort of crown round the body of the animal. The number of pieces forming what is termed the operculum usually amount to six, but they vary much sometimes, being only four in the usual state of these valves; each is divided on its surface into two triangular areas, the one in relief, the other hollow. And in the interior of these it is found that they are doubled in their superior or anal half by a vertical plate or separation, the extent and form of which is very important in distinguishing this singular species of shell. A reference to the article *Balanus* will also point out some other peculiarities not yet satisfactorily explained. Upon this subject, as well as many others connected intimately with the study of the science of conchology, we have been constantly tempted to enlarge; but a want of space must preclude us from dwelling longer, as a volume might be written, filled with ingenious hypotheses, and well-grounded deductions; our object, as has been more than once stated, being to induce a deeper research in others, rather than to broach our own opinions, or to write a voluminous treatise on the subject. So numerous are the pub-

lications adapted to every stage of the study, that those who have leisure to pursue it may take it up in any part of its progress. We flatter ourselves that we have, as concisely as the nature of science will admit, given an outline likely to prove serviceable to the student, without entering abstrusely into that portion of it which can only be interesting to the more finished naturalist. Having, in this place, confined ourselves more particularly to shells, as objects detached from their parents, much more remains to be said of them as properly connected with the animals; and this will be attempted under the articles MOLLUSCA and MALACOLOGY. We will now proceed to give a rapid sketch of the history of the science, or at least that part of it which includes the arrangement of shells alone, without any or very little reference to the animals. In which point of view, nearly all the naturalists of former times have written, and it may not be found useless or uninteresting to name the most celebrated authors, beginning from a very remote period of time down to that at which the science has assumed a new and higher order of claim to the attention of mankind.

That the study of natural history, and Conchology as a part of it, was not deemed beneath the notice of philosophers and statesmen in the enlightened ages of Greece and Rome, is proved by the valuable works still extant, the earliest of which is that of Aristotle, who flourished 322 years before the birth of Christ. It may be deemed a precious monument of accurate observation, and justly entitles him to the immortal name of the father of natural history. Like every other of his writings, this branch exhibits profound wisdom, and, even to the present day, his outlines of a systematic arrangement have been followed, and many of the genera of shells retained by succeeding authors. He first established the two great natural orders of univalves and bivalves, viewing shells, precisely as they are now considered, to be testaceous bodies, consisting of so many pieces or parts. The first were therefore termed *Monothyræ*, the second *Dithyræ*. To these he added a third order, in which were included the turbinated shells. Of these three orders he commenced a generic arrangement, distinguishing between their terrestrial or aquatic habitats, and even the immobility or locomotive power of the different species. These he separated into the *cinetica* or *acineta*. When we consider the period at which this great man existed, and the isolated nature of his labours, comparing them with the information he possessed in natural history, we may be truly astonished at his sagacity and wisdom. Though the acquirement of human knowledge is slow and progressive, Aristotle's Ostracodermata presents a valuable scheme of shells, and the sound well defined basis of all subsequent systems. Nor was the Macedonian philosopher the only great man of antiquity whose mind was alive to the study of natural history, and whose more important labours were diversified by its inviting charms. Pliny, Ælian, Athenæus, and Cicero, were each of them enthusiastic naturalists, and have left valuable proofs of their accurate observation of nature's productions, particularly in that branch we are now treating of. But this study, like all other liberal pursuits, was neglected in the darker era that succeeded, at least no evidence or the contrary has survived to this period; but in later ages, when the mists of Gothic ignorance, which had so long obscured the western horizon, dispersed,

the light of science dawned, and Conchology not only revived, but was encouraged by men eminent for learning and a superiority of mental acquirement, the admiration and envy of past centuries. Pliny, who lived in times more favourable to the cultivation of science (A.D. 80.), added but little to the information he derived from the writings of Aristotle. He certainly has added considerably to the number of species at that period described. The shores of the Roman empire, the Mediterranean, and Red Sea, presenting a rich field for the enterprising conchologist, he described, with great fidelity, the form and external aspect of shells, in which he has been followed by succeeding naturalists. But his arrangement was unphilosophical—his descriptions unsatisfactory—and he discovered but little matter important to the science beyond that which had long before been pointed out by Aristotle. Passing over the dark ages succeeding Roman greatness, in which science was degraded and ignorance deified, we find, to the end of the fifteenth century, little to instruct or interest us on this subject. Vicentius, in 1494, treats of the genera *Murex*, *Ostrea*, and some *Silices*, but without any systematic arrangement; and he has done no more than borrow from his predecessors, adding most largely from the superstitious absurdities of his days. In the sixteenth century, Belen, Rondeletius, and other authors, added something more to the information transmitted from the earlier ages. Their works, however, merely described new species, or pointed out what they considered a more natural arrangement of shells, many of them, however, venturing upon a general systematic classification materially different from the first outline sketched by Aristotle. We will therefore come to that period when Daniel Major may be considered as the first author who really occupied himself with a distribution of shells into a systematic form. This will be found in an Appendix to a Treatise on the Genus *Purpura*, by F. Columna, in the German language, under the title of *Ostracologia in Ordinem Redacta*, printed at Kiel in 1675. This appendix contains synoptic tables pointing out a natural association of genera established on the species observed by Columna, and consequently very few in number. To Major we are indebted for the division of univalves and multivalves, among which he places the bivalves.

In 1681, our countryman, Grew, in his *Museum Regium*, a descriptive catalogue of the Royal Society's collection, has published a systematic and synoptic table of the genera of shells, in which he includes all the testaceous envelopes of animals, and, without positively employing the present received terms of the science, established divisions of the single, double, and multiple shells, corresponding with our univalve, bivalve, and multivalve genera. In the first, he separates such as are rolled on a fictitious axis from those not so constructed; these are again divided into the species whose spires are visible or not, as in the *Nautilus*, *Coury*, &c. By this arrangement it is obvious that Grew distinctly pointed out those clear indications of animal structure forming the greater number of our present genera.

Sibbald, in 1684, in his *Scotia Illustrata*, goes back nearly to the divisions of Aristotle, principally considering the habitat of the shells, dividing them into terrestrial and aquatic, and the latter into marine and fluviatile species.

Lister, in 1685, still followed a similar arrangement; but, having the advantage of examining a far greater number of shells, his treatise is consequently more complete. His work, *Historiæ sive Synopsis Methodica Conchyliorum libri quatuor*, appeared in parts, and continued down to 1688. It contains, besides, a great number of plates, faithfully drawn and engraved by his daughters, the introduction of a distinction between the equality or inequality of the valves. He also appears the first to have attached a proper importance to the consideration of the hinges of bivalves.

Tournefort, an eminent French botanist, who died in 1708, attempted to facilitate the study of shells, which he designated under the general name of *Testacea*, defining them as the envelopes of certain animals possessing the hardness of a tile, or baked earthen vessel; but his method was only known for the first time by a work of Gualtieri, published in 1748. Tournefort substituted the names of *Monotoma*, *Ditoma*, and *Polytoma*, for those of the present day. Among the *Monotomes* he established the distinction between the univalves, properly so called, and the spirivalves and fistulivalves, and his generic characters are considerably guided by the form of the aperture. In his class *Ditoma* he is said to have been the first to establish a division between the bivalves that closed perfectly (*Clausæ*) and those which partially gaped (*Hiantes*). He also paid attention to the position of the hinge. In his *Polytoma* he, however, confounds the *Echini* and *Balani*.

Rumphius, in 1711, described a considerable number of shells from the Indian seas, but he did not add much to the science of Conchology. He did not even separate the bivalves from the multivalves; and with respect to the univalves, he considered them simple or turbinated, as distinguished by Aristotle. He, nevertheless, indicated some well-defined divisions, such as the *Strombus*, *Voluta*, and the porcelanic genera.

Lang, in 1722, proposed a new but partial conchological distribution, merely treating of marine shells; but notwithstanding the pompous enunciation of his work, which is too long to be here inserted, he added very little to Lister's arrangement beyond examining the equality or inequality of the valves, and the relative positions of the summits. He also paid rather more attention to the form of the apertures in univalves, and of the summits of bivalves, in these he likewise established a division of anomalous species.

J. Ernest Hebenstreit, in 1791, published a dissertation, entitled, *De ordinibus Conchyliorum Methodicâ Ratione instituendis*, in which there are but few important novelties. He, nevertheless, among the univalves, pays more attention to the spine than his predecessors had done; and in the bivalves, his first division is characterised by the presence or the absence of the hinge, as then considered.

Phillip Breyn, in 1830, first drew the attention of conchologists to a distinctive character of shells, up to that period overlooked, this was the number of cells or separations in univalves, whence proceed the names *polythalamia* and *monothalamia*.

Gualtieri, an Italian author, in 1742, published a work which still possesses some degree of reputation, from the great number of shells figured. They are, however, but indifferently executed, and fall far short of modern illustrations. As a work of scientific reference, it includes all, or nearly so, that his predecessors

had introduced in the way of classification, without adding much improvement or novelty; we shall not, therefore, dwell upon it, but merely observe, that though he indicates many generic divisions, they are not established on a solid basis, and have afforded but little to guide subsequent writers.

D'Argenville, in the same year, published in France the first edition of his work, *De l'Histoire Naturelle éclaircie dans Deux de ces Parties Principales, la Lithologie et la Conchyliologie*, a work like that of Gualtieri's, much admired for its plates, but containing little scientific improvement to recommend it. In nearly all he has done, Lister's system was his guide, and when he ceased to consult or follow that authority, he has invariably made matters more obscure, though he is most unjustly critical in his observations on that author.

Klein, immediately after D'Argenville, published a work entirely systematic, but without the advantage of good illustrations. His object appears to have been that of overturning and changing all Linnæus attempted to establish; this being unsupported by the reasons of subsequent writers, render his work a mass of confusion and little worthy of reference. He certainly proposed, rather than established, a great number of genera since adopted; but the characters assigned to them were so vague, and so badly circumscribed, that his writings have nearly fallen into oblivion. His classification of the *Echini*, however, merits praise as being the first attempt, though extremely deficient in execution.

Adanson, in 1757, published his voyage to Senegal, and, although the first editions of Linnæus's *Systema Naturæ* had already appeared, we place his information in a point of priority, because it appears quite evident that great naturalist must have derived a considerable portion of his general fixed principles of conchology from Adanson; he also may, more properly, be considered a writer on malacology, since he examines shells, with their animal architects. By this much innovation was introduced into the science of conchology, properly or abstractedly so called in this article. Thus, besides an elaborate study of each of the parts of shells, and a description of the characters, he may be said to have formed a distinct system for each. Among other novelties in confirmation of this he divides bivalve shells according to the number of their muscles, or their attachments; and above all, he has introduced the consideration of the operculum, an important feature of the science, up to his time altogether neglected, or nearly so, by subsequent authors. From this consideration, he established in the *Helices* two marked sections: the first, univalve snails; the second, operculated species, which he considered, though very erroneously, as forming the gradation to bivalves. He appears also to have been the first who classed the *Patella* with the *Chiton*, his section of multivalve conchs containing only the *Pholas* and the *Teredo*.

Linnæus, in his first edition of the *Systema Naturæ*, proved that he was not master of this part of natural history; but in the edition following Adanson's work, he exhibited the possibility of applying the same principles which he had discovered and so advantageously employed in botany. He, nevertheless, created no very novel consideration in the first divisions; nor, indeed, in the secondary ones, since he divides shells into multivalves, with which he begins, and in which he places the *Chiton*; bivalves and univalves, after-

wards sub-divided into turbinated or not turbinated; but he has the lasting merit of having introduced, in the description of their characters, in their circumscription, and in the creation of a conchological language, that brevity and clearness which will ever entitle him to be considered the model and master of systematic naturalists; from which nothing can obviously detract, except the bad taste and unaccountable feeling which but too frequently marks his nomenclature—setting modesty at defiance, and making greybeards blush.

About this period Martini commenced his gigantic book, which was continued and completed by Chemnitz in 1788. This we consider rather as a collection of the figures of shells, than as a true system of conchology, the arrangement partaking of Gesner and Lister's plans, with regard to the first divisions; and the others formed from the habitat of the animals, he nearly follows the Linnæan system, and his great divisions may be considered simple, and not breaking their natural gradations in any very remarkable degree. As a work containing a greater number, and, generally speaking, more correctly drawn illustrations of shells, nothing combining these united advantages has ever yet appeared; its great price, however, will ever render it a work of luxury more than utility.

Dacosta, in 1776, published an original, and it may be said, true system, under the title of Elements of Conchology. It differs evidently but little from that of Linnæus, though he attaches more importance to the predominant characters drawn from the form of the aperture in turbinated univalves, and the hinge of bivalves; he is the first writer who suggested the propriety of changing many of those terms used by Linnæus, of which we have already pointed out the indecency; he has also considerably augmented the number of genera of that naturalist, each of which are illustrated by tolerable figures; but though his work may be deemed highly instructive, he has not introduced into the science any very strikingly new consideration.

We pass over in silence several authors, such as Müller, Born, and others, who have added little or nothing to the science of conchology, in our present view of it. Those of them who have examined shells with reference to the animal, will be noticed hereafter, and we then come to the French School of Conchology, in which it appears to us more has been done than in any other, towards raising the study of this interesting portion of creation into its well-merited rank of natural sciences; and we must be permitted a slight digression from the immediate article under consideration, to state, that although we are not wedded to the system of any one author, blind to the faults of all, or insensible to the improvements of time, we must, nevertheless, adopt some rule of conduct, some guide for our opinions, and we do not hesitate in preferring a system, matured as it now is upon the admirable model furnished by Cuvier, and other great naturalists, his disciples: like every human effort it is incomplete, often erroneous, but as a whole, the most perfect yet constructed; and, from being founded on the broad basis of truth and common sense, will last to the end of time, becoming more confirmed by every day's experience of its correctness.

Brugnière, in 1792, is the first author we shall name, as having taken the lead in forming the modern science of Conchology. We must all along be understood to allude to it, more particularly as relative to the consideration of shells as isolated bodies, the view we have confined ourselves to in this article.

Brugnière closely followed Linnæus, but it is due to him to acknowledge that he has much more clearly characterised and circumscribed the genera, which has necessarily led to considerable increase of their number. Death having deprived the world of the benefit that would have resulted from his labours early in the commencement of his scientific career, the small number of genera he lived to describe will prove the justness of his reasoning. His characters were well defined, clearly explained, and, what is extremely important in this as well as every other study, they are perfectly consistent with each other. He may be considered the first naturalist who has introduced into conchology that exact precision of detail so necessary to be observed, particularly with reference to those minute indications required in a comparison between recent and fossil shells; in other respects he does not claim much praise as having introduced any very marked improvement in the Linnæan system.

De Lamarck improved upon his friend Brugnière's method considerably, not only by considering the shell as a part of the animal constructing it, according to the opinions of Guettard, Adanson, Geoffroy, Müller, Poli, Cuvier, De Ferussac (father and son), De Blainville, and others, but by the great number of new generic divisions, a more rigorous terminology; and by the introduction of the muscular impressions in bivalve shells, as the base of one of their principal divisions, which, in 1810, was adopted by Ocken. Lamarck, nevertheless, fell into the error of classing the *Chiton* with the *Patella*. In general it may be observed that he has entirely departed from the divisions of previous conchologists, established upon the number of pieces composing the shell; and that it is rather the combined form of the shell which he examines, to establish his four first divisions into sub-spiral, cardiniferous, sub-coronal, and vermicular; and, in fact, he could no longer admit the univalves, bivalves, and multivalves, since he places the *Chiton* amongst the sub-spirals, which certainly no one wishing to arrange a collection of shells would have thought of. In this arrangement, Lamarck has, *if possible*, placed shells too closely in scientific connexion with their animal inhabitant, which, though it renders the subject far more interesting to the philosopher and anatomist, occasions the science to become more difficult to those who have the same motive for studying it, and merely look at it as a mental relaxation from other worldly pursuits. During the period that was occupied, in bringing to perfection and publishing Lamarck's system, other conchologists followed Brugnière's extended view of the Linnæan system, and Donovan, Montagu, Bosc, &c., published their arrangements.

Denys de Montfort, in 1808, brought before the public his Systematic Conchology, including only the univalve shells; but he carried his generic subdivisions to a ridiculous excess, by wishing too narrowly to define extremely minute characters; this, doubtless, arose from his having been the first author who thought science demanded the description of microscopic shells; but though his work, were it generally useful, might easily be modified, it is not considered an authority at this time. Many of his genera are, nevertheless, adopted.

De Blainville, a French naturalist, and an excellent anatomist of Cuvier's school, published his first classification of shells in a memoir read at the Philomatic Society in 1812. This was founded on a reference to

the animals, and not their simple coverings; but he has the merit of having, for the first time, introduced a consideration of shells in a new point of view, that of forming the essential protection of the organs of respiration, from whence followed, to a certain extent, the general form and position of them; and thus, by combining as it were the double function of the shell and the animal, to be able to pass easily from the one to the other, by calling the attention to the indications of a new character, founded on the symmetry or non-symmetry of univalve shells, with regard to the respiratory organs. He also replaced the *Chiton* with the univalves, and in many other instances has adduced very satisfactory reasons for having re-united many of the genera of Lamarck and other naturalists, improperly and needlessly sub-divided by them.

This brief sketch of the progress of conchological study, as a science, must be considered extremely incomplete, since we have professedly named only a small portion of the labourers in that field, and only such as have in some degree attempted a new systematic arrangement of shells alone: to have enumerated each new idea, each novel alteration in the progress of time since the days of Aristotle, would have occupied space allotted to more interesting matter, and could not have conveyed any useful information, particularly to the scholar; to have given a mere catalogue of authors, and the various views they have taken on the subject, for the same reason is useless, and as Conchology in future must be combined with a reference to the animals constructing shells, the system will be described more amply under the article MALACOLOGY.

The object of this work is to point out briefly all that may be deemed solid information on every branch of natural history, and not to enter into controversial points of opinion, or to wage war against those with whom we may have the misfortune to differ. Every man has, doubtless, a right to his own set of ideas, but it is deeply to be regretted, when his ignorance, or its offspring, vanity, induces him to question with acrimony another's different view of the same subject; to split hairs with cannon balls, and to write all men down as asses, who presume to differ with him in opinion. This, unhappily, but too frequently is exhibited by modern naturalists, and it is the more remarkable, since the study of natural history should lead to every good feeling of human nature—unite mankind in one common cause, and contribute to one great end—that of adoring the Author of all these marvellous productions; the least of which, if properly received, would humble the pride of the most arrogant of mortals; by proving to him, that the ingenuity of ages can only produce clumsy imitations of anything bearing the imprint of Almighty wisdom.

**CONDYLURA.** A genus of mammalia, belonging to the insectivorous division of the order *Carnassier*, and, in general habits, bearing some resemblance to the moles, but striking from them in many particulars. The most differing of the external peculiarities is their tail, from the appearance of which the genus has obtained its name. It is formed with a series of nodes or enlarged round protuberances (*condyles*), which give it some resemblance to a necklace of beads.

The characters are: six incisive teeth in the upper jaw, of which the two in the middle are very large, bent into a sort of spoon-shape on their inner sides, and with their cutting edges a little oblique; the two external incisors, in this jaw, are conical, and bear

some resemblance to canines. There are four incisors in the under jaw, which project forward with a curve, and give a sort of spoon-shape to the exterior part of that jaw; also, to each side of the upper jaw there are three false molars formed, each of two plates of enamel, and having pointed tubercles on their inner edges, and a groove on their outer. There are four false molars in each side of the lower jaw. The canines in the upper jaw are large and strong for the size of the animal, but those in the lower are very small. They have no appearance of external ears, and their eyes are remarkably small; their fore-feet are short and broad, with five toes upon each, furnished with claws well adapted for digging in the ground. The hind-feet, which are longer and more slender, are also each provided with four toes.

This genus of animals is understood to be peculiar to North America, and in its habits to bear a very considerable resemblance to the moles of the eastern world, that is to say, they spend the greater part of their time under ground, and are understood to subsist chiefly upon earth worms, earth insects, and larvae. Two or three species have been mentioned, but only one is known with certainty, and of its manners we know but little.

*Star-nosed Condylure* (*Condylura cristata*). This is the *Sorex cristatus* of Linnæus, but it is more nearly allied to the moles than to the shrews, and therefore, the name is inapplicable. The knots on the tail and also the very remarkable form of the termination of the muzzle, readily distinguishes this from any other animal. The muzzle is very long, supported in the centre by an axis of bone, in the same manner as the snout of a pig, and like that, it has the nostrils central in the extremity, so that we may conclude that its sense of smelling is of considerable service to it in the finding of its food; but the extremity of the snout is very different from that of any other animal. It is in the form of a star, consisting of cartilaginous rays which are rose-coloured, have their surfaces granulated, and are about twenty in number; two on the middle of the upper part and four on the under, are much longer than the rest. All the points of which this star-like rose is composed, are moveable at the pleasure of the animal; but from the peculiarity of their form, we may naturally suppose, that this description of digging instrument, though it may make its way faster than the entire snouts of other digging animals, cannot force its way so readily through compact mould, and thus, the animal is adapted to those alluvial deposits in the American forests, which are formed rapidly, consist in great part of leaves, and are very spongy in their texture. It is possible that some of the elongated filaments may assist the animal in feeling for its food underground: but we are not so well informed of its habits as to be able to decide upon particulars.

The feet bear some resemblance to small hands, they are broad, naked, and covered with scales; and the nails, though longer than those of the mole, are more slender and not so treacherous on their under sides, which farther shows that this animal is adapted for making its way through softer soil than that with which our moles have to contend. This is still farther indicated by the structure of the hind feet, which are long and slender, differing in form from those of most other of the smaller burrowing animals, whether of Europe or any other part of the world. All the phalanges of the hind toes are free, so that the sole of

these feet consists of the metatarsal bones only. This structure of foot enables the animal to spread out its hind toes till they are as wide apart from each other as those of a free-toed bird; but whether the animal uses the extensive resistance which it can obtain by this means, in pushing through soft earth or through tangled vegetables, has not been ascertained. The tail is remarkable for having transverse folds of the skin, corresponding to the different vertebrae, and in the intervals, between those folds, there are long hairs more thinly set than in any other part of the body. The colouring of the fur upon the body is nearly the same as that of the common mole, and it is glossy, and difficult to be soiled or wetted while the animal is alive; but its texture is not so delicate as that of the fur of the European mole. The whiskers do not spread out to the sides as in most small animals, but project forward. On the feet there is a large membranous scale on the inner surface, and a few scattered hairs on the outer. In its general form this animal indicates more activity in motion, though probably less strength in proportion than the mole; but its manners are so imperfectly known, that no very good account of its economy can be obtained. It is not large, being about four inches long in the body, and with a tail about half that length.

*Condylura longicaudata*. This species is still less known than the former; it inhabits the northern parts of America, but whether exactly the same kind of places as the other is not said. It is without the nasal crest; the tail is rather longer than half the body; the fore feet are similarly formed to those of the moles, but the hind feet are long and slender. The feet are scaly, thus indicating a digger in the ground, an inhabitant of watery places, or both.

The time of pairing, the period of gestation, the number of young, the state in which they first appear, the length of time that they are suckled, their age at maturity, the length of their lives, and all of what may be termed their domestic history, is entirely unknown; neither are we able to tell, with any certainty, what is their principal function, or the importance of that function in the general economy of nature.

CONDOR. See VULTURE.

CONIA (Blainville), *Asemus* (Ranz), a genus of mollusc, separated from the family balanides in consequence of a particular combination of the number of pieces forming the tube. The shell is conical, depressed, the coronary part formed of four pieces only, more or less distinct, nearly equal, and usually striated from the summit to the base, with or without distinct areas. The support is flat, very thin, or altogether membranous. The operculum articulated, pyramidal, composed, as in the balani, of two pieces on each side, moveable, or as it were soldered to each other.

The genus has been subdivided into the species whose valves are pectiniform, with the areas and the divisions very distinctly marked. The second division includes all those in which the valves are but little or not at all distinct, and without any traces of areas. The animal is precisely the same as that of the balanus.

CONIFERÆ. The fir family. A natural order of dicotyledonous plants, containing twenty or thirty genera, and nearly two hundred known species.

Considerable discrepancy of opinion existed for a long time among botanists in regard to the structure of the coniferæ; but the researches of Richard and Brown have dispelled all difficulty on the subject,

and have enabled us to comprehend fully the organization of this most interesting family. The order occupies a place intermediate between the cellular and vascular plants. To the former it is connected by means of *Lycopodiaceæ*, with which it agrees in the aspect of the stem and leaves, and in the nearly total absence of spiral vessels; while it is connected with the latter through the intervention of the oak, willow, and birch tribes, with which it agrees in having an amentaceous inflorescence. It bears a very strong affinity to *Cycadeæ*, resembling this family in the form of its naked ovula, in its mode of inflorescence, in the arrangement of the veins of the leaves, in the imperfect formation of the spiral vessels, and in having the vessels of the wood perforated by numerous holes.

The name *Coniferæ* is derived from the fruit, which is in the form of a cone. The essential characters of the order are: Flowers, monœcious or dioecious: *Sterile flowers*, monandrous or monadelphous, each floret consisting of a single stamen, or of a few united, collected in a deciduous catkin about a common rachis; anthers two or many-lobed; pollen large: *Fertile flowers*, generally in cones, sometimes solitary; ovary in the cones spread open, and having the appearance of a flat scale destitute of style or stigma, and arising from the axil of a membranous bractea; ovules naked, in the cones in pairs on the face of the ovary, having an inverted position, in the solitary flowers erect; fruit consisting either of a solitary naked seed or a cone; seeds with a hard, crustaceous covering; embryo in the midst of a fleshy and oily albumen, with two or many opposite cotyledons.

The plants belonging to this order are resinous trees or shrubs with branched trunks, and linear, rigid, entire leaves, furnished with parallel veins, and sometimes sheathed at the base. They are found in various and very different parts of the globe; some inhabiting the cold regions of the north, and others growing in the hottest parts of the Indian Archipelago. They abound in the temperate climates of Europe, Asia, and America, and many species are furnished by the Australian continent.

The order has been divided into three sections: I. *Abietinæ*, the pine tribe, including the genera *Abies*, fir or spruce; *Pinus*, pine; *Larix*, larch; *Cedrus*, cedar; *Cunninghamia*, *Dammara*, *Araucaria*, &c. II. *Cupressinæ*, the cypress tribe, comprehending the genera *Cupressus*, cypress, *Juniperus*, juniper, *Thuja*, &c. III. *Taxinæ*, the yew tribe, including *Taxus*, yew, *Ephedra*, *Podocarpus*, &c.

All the species of this extensive family are raised from seeds. The cones are gathered in winter and exposed to the sun, or the gentle heat of a fire or kiln. In this manner the scales are opened, and the seeds easily taken out. The cones of the Scotch pine, the common spruce and larch, require kiln heat; while those of the Weymouth pine, silver fir, and balm of Gilead fir, give out their seeds easily without the aid of artificial heat. So long as the cones are kept close the seeds remain uninjured, and they ought not to be opened long before the seeds are sown, otherwise germination is apt to be prevented. The seeds are sown in the months of March and April, in soft rich soil. They ought at first to be screened from the sun and protected from birds. They require a covering of earth, varying from one-fifth of an inch to an inch and a half. For the spruce fir one inch is required, for the silver fir, and balm of Gilead fir, the depth of soil varies from one-half to three-

quarters of an inch, while for the American species one-fifth only is requisite. The seeds of most of them, except the stone pine and a few others, come up very soon. They are thinned and put in rows at the distance of four or five inches, and three or four in the row. After being a year in these rows, they are removed to others two feet distant from each other. After being two years in the seed-bed, and having attained the height of six or seven feet, they are finally planted out, and great care is requisite in the removal not to allow the roots to be long exposed, for though the plants are hardy when grown up, they are very tender when young. Fir plantations should be regularly thinned from the time the trees are six or seven feet high, until they attain the height of twenty or thirty feet. At this time the trees, if they are Scotch, spruce, or silver firs, ought to be at least twenty feet distant from each other. Larch firs require more shelter, and ought to be a little closer. Firs, in general, require plenty of room, in order that their branches may expand fully. They cannot be pruned, on account of the large quantity of sap which they contain, and which flows freely from the slightest incision, weakening the tree much, and sometimes stopping its growth for several years.

Various resinous products are furnished by the fir, pine, and larch tribe. They may be divided into—1, those which are yielded by spontaneous exudation, such as Briançon manna, &c.; 2, those which are got by making wounds into the wood through the bark, as the various kinds of turpentine; 3, those obtained by decoction, as the essence of spruce, and 4, those procured by fire, as tar and pitch.

The common oil of turpentine of the pharmacopœias is procured by distillation, and is the product of several species of pine. It is a transparent, limpid, volatile fluid, having a hot pungent taste, and a powerful odour. It is highly inflammable, and is lighter than water. Its properties, in general, are of a stimulating nature, and it is much used in medicine. It acts upon the bowels, and increases the secretion of urine, imparting to it a smell of violets. In large doses it is particularly beneficial in tape-worm. It is also used in epilepsy and in inflammation of the bowels. When given in large doses, it produces temporary intoxication. Externally it is employed in palsy, nervous pains and spasms, and in burns. It is also said to be useful in checking bleeding. It has been lately employed, with great success, in the process of boring, or cutting glass, as it is said that a common awl may be forced through a plate of glass, provided oil of turpentine is kept constantly applied.

The residuum of the distillation of oil of turpentine receives different names according to the mode in which it is conducted. When the distillation is performed without addition, and continued till all the essential oil is driven off, then there remains colophony; but if water is added to the mass while fluid, or thoroughly blended with the rosin by agitation, then we procure yellow rosin.

In procuring tar, a conical cavity is dug in the earth, which communicates with a reservoir at the bottom, and billets of fir are then placed so as to fill the cavity and form a cone above it. The mass is then kindled at the top, and covered over with turf. In this way the combustion goes on slowly, and all the liquefied tar accumulates at the bottom. By boiling the tar for a long time, all the volatile matter is driven off, and a substance called pitch is left.

Tar or pitch ointment is applied externally in ring-worm and various cutaneous diseases. Tar water has been recommended as a diuretic and sudorific. Tar fumigation has been considered beneficial in consumption, by promoting expectoration.

*Cedrus Libani*, cedar of Lebanon, (*Pinus Cedrus* of Linnæus), is a native of the coldest parts of the mountains of Libanus, Amanus, and Taurus. In these places the tree formerly grew in large quantities. The forest of Lebanon was famous in the days of Solomon; and in his time cedars were said to be "as the sycamores that are in the vale for abundance." Nowadays, however, cedars are by no means common in Palestine. A few still exist, some of them nine feet in diameter.

The cedar is a large, wide-spreading tree, not so lofty as is frequently represented, and as Milton would make us believe, when he says—

Over head upgrew,  
Insuperable height of loftiest shade,  
Cedar, and pine, or fir, or branching palm.

The timber of the cedar is very indestructible, and was anciently much used in the decoration of temples. In the temple of Apollo, at Utica, some beams of Numidian cedar are said to have been 1200 years old. This wood was also employed in forming statues; and it is supposed that the famous statue of Diana at Ephesus was constructed of it. The wood was also used in embalming and in preventing putrefaction. The tree yields a saccharine resinous substance.

The cedar was introduced into Britain in 1683; and in some parts of England, as at Witton Park and Zion House, it thrives well. In the Garden of Plants at Paris, there is a fine specimen of the tree which was planted by Jussieu.

The cones of cedar must be kept for a year before the seeds are taken out, on account of the softness of the seeds and the resinous matter with which they are surrounded. The cones are imported from the Levant, and the seeds retain their vegetating powers for many years.

*Cedrus deodara*, sacred Indian cedar, grows on the high mountains of Nepal and Thibet, at an elevation of 10 or 12,000 feet above the level of the sea. It is regarded with veneration by the Hindoos, and furnishes durable and valuable timber.

*Juniperus communis*, common juniper, is common in many parts of Europe. A dwarf trailing variety of it is found on the mountains of Wales, Scotland, and Ireland. It is an evergreen shrub, furnishing a hard, reddish wood, which serves for veneering. Its bark is made into ropes. Its berries are imported in considerable quantities from Holland and Italy. They have a strong, disagreeable smell, and a warm, pungent, bitterish taste. They consist of essential oil and sweet mucilaginous matter. This oil, which is of a green colour, is separated by distillation, and gives the peculiar flavour and properties to Hollands. Gin was formerly made in imitation of Hollands, by the addition of juniper; but it is now made from whiskey rectified on turpentine.

Both the berries and the tops of the juniper are used medicinally. They possess tonic, stimulant, and diuretic properties. These qualities are owing to the essential oil which they contain. An infusion of the tops has been used in dropsy. The juniper is the badge of the clan Murray in Scotland.

*Juniperus sabina*, common savine, is a low evergreen

shrub, found native in the south of Europe, and frequently met with in gardens. Its leaves have an acrid bitter taste and a strong smell, and the whole plant yields an essential oil, which possesses very active qualities. The general properties of the plant are stimulant and diuretic. It is prescribed sometimes in cases of worms and gout. An ointment prepared from the leaves, of a green colour, and having the odour of the plant, is used as an issue to promote the discharge from blistered surfaces.

*Juniperus Virginiana*, red or Virginian cedar, is a tree of great size and beauty. It sometimes grows to the height of forty feet, and furnishes valuable timber, which is used for parts of buildings, and other important purposes. It is found in North America and the West Indies. The heartwood is of a red colour, and moderately soft, and is used in the formation of common cedar pencils.

*Juniperus oxycedrus*, sharp cedar, or brown-berried juniper, is a native of Spain, the south of France, and the Levant, and was used in ancient times in the formation of statues. Its wood furnishes, by distillation, an empyreumatic oil, called cedar oil, which is used as a vermifuge, and as an article of veterinary medicine.

*Juniperus lycia* yields a gum-resin, similar to olibanum.

All the junipers are raised from seeds, which ought to be sown in a light soil as soon as they are ripe.

Another important genus of this extensive order is *Cupressus*, or cypress.

*Cupressus sempervirens*, common, evergreen or funeral cypress, is a native of Cyprus and Crete, and grows on Mount Ida. It is common in old gardens, and is often planted in clumps of evergreens. In consequence of the gloomy hue of the leaves, branches of it were formerly placed before the doors of the deceased, and were used at funerals. It furnishes a valuable and durable wood, which resists the attacks of insects, and is used in Crete, Malta, and the Levant for the purposes of building. The tree was planted by the Moors round their palaces, and by the ancient and modern Romans in their villa gardens. The doors of St. Peter's, which lasted from the time of Constantine, for a period of 1100 years, were made of cypress wood. This is supposed to be the wood of which the ark was made, and called in the scriptures Gopher or Shittim wood. Cypress wood was used by the Greeks in the time of Thucydides for the coffins of their eminent warriors, and we find the chests of the Egyptian mummies sometimes made of it.

*Cupressus thyoides*, white cedar, is a middle-sized evergreen, found native in North America and China. In the United States it occupies large tracts of country, denominated cedar swamps. Its wood is soft, of a red colour, and diffuses an aromatic odour.

*Taxus baccata*, common yew, is a native of Britain, the northern parts of Europe, and North America. It is frequently cultivated in pleasure grounds, and used to be clipped and fashioned in a most fantastic and remarkable manner. From being considered a lasting emblem of immortality, it was frequently planted in churchyards, and the sight of it is consequently apt to excite gloomy and melancholy ideas. Pennant mentions a yew in a churchyard in the Highlands of Scotland, at the entrance of Glen Lyon, the remains of which measured fifty-six feet and a half in circumference. In Wales and Ireland twigs of the yew-tree are often carried at funerals.

The yew was formerly looked upon as possessing poisonous and deleterious properties, and was said to prove fatal to any one who slept under its shade. Hence it acquired the appellation of "deadly yew." These notions, however, are now found to be totally erroneous. The berries of the yew, which are of a red colour, are quite innocuous, and do not possess the poisonous qualities formerly attributed to them. The leaves, however, are found to possess slight narcotic properties. The wood of the tree is red, hard, and beautifully veined. It is used by cabinet-makers, and was in early times imported in large quantity for the purpose of making bows. It was in those days planted extensively to furnish bows to our warlike ancestors,

Who drew,  
And almost joined the horns of the tough yew.

In later times, since archery is less practised, the cultivation of the yew is less attended to.

The tree is propagated by seeds. It is well known as the badge of the clan Fraser.

*Thuja occidentalis* is the common arbor vitæ of our gardens. It is a native of Canada and Siberia, and sometimes acquires the height of thirty or forty feet. The first specimen of the tree brought to Europe, was planted in the royal garden at Fontainebleau, in the reign of Francis the First. The wood is used in the formation of boats and inclosures, as well as in the construction of houses. In England it is frequently used by turners. The leaves are said to have been prescribed in rheumatism. Another species, *Thuja orientalis*, is found in China. *Thuja articulata*, or jointed thuga, yields a yellow brittle resinous substance, having an acrid aromatic taste, to which the name of sandarach is applied. It is employed as a varnish. This resin is stated by some authors to be a product of the common juniper.

The coniferous or cone-bearing plants found in Australasia are chiefly included under the genera, *Araucaria*, *Dammara*, *Dacrydium*, *Cunninghamia*, and *Altingia*.

*Araucaria*, or *Altingia excelsa*, Norfolk Island pine, is an immense tree, which sometimes attains the height of two hundred feet, with a circumference of thirty feet. The wood which it yields is not valuable, on account of its want of durability and solidity. Its bark yields a resinous substance. It does not thrive well in the open air in this country.

Species of the genus *araucaria*, similar to this, would appear, by the researches of fossil botanists, to have existed formerly in Britain. *Araucaria Dombeyi* or *imbricata*, is a South American species, the wood of which is valuable, and its seeds are eaten as articles of food when fresh.

*Dammara orientalis*, Dammara pine (*Pinus Dammara* of Lambert), is a native of Amboyna, and furnishes a peculiar resinous matter. Some say that liquid storax is procured from it. *Dammara Australis*, Cowdie pine, or Kawie-tree of New Zealand, attains the height of two hundred feet, and yields a light compact wood, free from knots. *Dacrydium taxifolium*, or Kakaterro, another New Zealand pine, is said to equal the Cowdie pine in height. The branches of this pine yield spruce.

We have thus endeavoured to describe some of the plants contained in this extensive order. They are of great interest and importance to man, both on account of the valuable timber which they furnish, and

the useful secretions which are procured from them. Woods and forests, both in cultivated and savage countries, consist in most instances of trees belonging to this family. They are remarkable for their size, the rapidity with which they grow, and the majestic appearance which they present. They are almost invariably natives of the northern, although occasionally found in the southern hemisphere, and may be said to supply, by their dense persistent leaves, the place occupied by the evergreens of warmer climates.

**CONIROSTRA**, one of the divisions into which Cuvier arranges his great order of Passerine birds, and which expresses generally that the bills of such birds are more or less of a conical form, that is, thick at the base, and tapering to the point. For a more particular account of the propriety of using the name, and of the place which the birds hold in the system, see the article *BIRD*.

**CONIUM** (Linnaeus). Is the well-known and dreaded hemlock. The spotted hemlock of this country is accounted highly poisonous, though it is useful in some cases when applied outwardly. Two of the South American species, namely, the *C. arracacha* and the *C. moschatum*, are both cultivated there for the sake of their large parsnep-like roots, which are useful articles of diet among the natives. The *arracacha* is now under a trial of naturalisation in this country, with the expectation that, if hardy enough for our climate, it will prove an important addition to our stock of culinary vegetables.

**CONNARACEÆ**. A natural order of dicotyledonous or exogenous plants, containing five or six genera, and between twenty and thirty known species.

This family is by some authors looked upon as a distinct order, while by others it is considered merely as a section of *Terebinthaceæ*. It is nearly allied to *Leguminosæ*, from which it is distinguished by the radicle being at the extremity most remote from the hilum. From *Burseraceæ*, *Cassuviæ*, and other terebinthaceous orders, it differs in the total want of resinous juice.

Considered as a separate order, its essential characters are: Flowers hermaphrodite, rarely unisexual; calyx five-partite, regular, persistent; petals five, inserted on the calyx, with an imbricated, rarely valvate æstivation; stamens ten; filaments usually monadelphous; carpels five, one-styled, distinct, sometimes solitary by imperfection; seeds erect, from the bottom of the cell, in pairs or solitary, with or without albumen, often axillate; radicle superior, at the extremity opposite the hilum; cotyledons thick and fleshy in the seeds without albumen, foliaceous in those with albumen.

The plants belonging to this order are trees or shrubs, with terminal and axillary flowers, in racemes or panicles, and compound alternate leaves, without dots or stipules. They are found in the tropical regions of Asia, Africa, and America. Little is known in regard to their properties.

The chief genera of the order are: *Connarus*, *Omphalobium*, and *Cnestis*.

**CONOCARPUS** (Jacquin). A genus of shrubs and trees, natives of the West Indies and South America. Linnæan class and order *Pentandria Monogynia*, and natural order *Combretaceæ*. Generic character: flowers in a head; calyx pitcher-shaped, five-cleft, and deciduous; stamens five (ten), inserted in the calyx; anthers heart-shaped, two-celled, bursting lengthwise; style and stigmas simple, scaly,

corky, one-seeded. This is called the button-tree in Jamaica, and has been many years in European collections. It thrives in a mixture of loam and moor earth, and is propagated by cuttings.

**CONOCEPHALUS** (Thunberg). An exotic genus of orthopterous insects, belonging to the section *Saltatoria*, and family of *Gryllidæ* (Leach), or grasshopper, with long slender antennæ.

**CONOLITES** (Lamarck). A fossil genus of molluscs. The shell is nearly straight, or only slightly curved, the sides very thin, the cavity filled, through its whole length, by a succession of simple chambers, increasing from the first to the last, which is at a great distance from the opening; the siphon is central or marginal. The genus is subdivided into four species, but the distinctions are extremely minute, and considerable doubts exist as to the propriety of separating it from some others of the family *Orthocerata*. Authors have variously named the species, which confirms the difficulty of distinguishing them. De Montfort calls one *Acheloite*, another *Amimomius*, and a third *Thalamulus*.

**CONOPIDÆ** (Leach). A family of dipterous insects, belonging to the section *Athericera*, having for its type the genus *Conops* of Linnaeus, and distinguished by the mouth being elongated into a slender, pointed, and elbowed proboscis. The nerving of the wings is very simple, and resembles that of the domestic fly. The family comprises the genera *Cephænes*, *Conops*, *Zodion*, and *Myopa*, having the body long and narrow; and *Bucentes*, *Prosenæ*, and *Stomoxys* (forming the family *Stomoxydæ* of Meigen and Stephens), having the body short, and very much resembling the common fly.

The structure of these different genera are very diversified, as are also the habits of such as we are acquainted with. The larvæ of conops are stated to reside in the abdominal cavity of the humble bee (*Bombus*), and St. Fargean states, that he had noticed the conopides introducing themselves into the nests of wasps, so that he supposes that the larvæ of the former, in all probability, subsist upon those of the latter. Latreille also says, that *Conops rufipes* has been observed in a recently developed state, with the wings still soft, to come out of the body of a bombus. An apod larva found in the body of the stone humble bee (*Bombus lapidaria*), and considered by Latreille and others to have been that of the same species of conops, has been made the subject of a valuable memoir by Messrs. Audouin and Lachat, contained in the first volume of the *Memoirs of the Natural History Society of Paris*. The conops, when arrived at the perfect state, frequent flowers, as do also the zodions and myopæ. M. Robineau Desvoidy has informed M. St. Fargean, that a larva which he had found in the body of a caterpillar produced a fly of the latter genus.—In like manner the larvæ of *Bucentes*, observed by De Geer, had been reared in the chrysalis of a moth, although the perfect insect, as well as the prosenæ, live upon flowers. The genus *Stomoxys* comprises that tormenting insect which is so often mistaken for the domestic fly, and which does not cease its irritating attacks until the first frosts of winter. The name of the genus indicates the cause of this irritation, being derived from the Greek, and signifying sharp mouth; the proboscis being very acute and horny, so as to enable it to puncture not only the skin of man, but also the tougher coats of the ox and horse. After it has filled itself with its sanguinary repast, the

wound does not at once close, but continues to bleed for a time. The common species (*Stomoxys calcitrans*) is most abundant in autumn, hence the origin of the common error that at this period of the year the domestic fly is most tormenting. Some individuals of this species (probably impregnated females) hide themselves during the winter, becoming torpid, sometimes as many as a score may be found packed closely together in the stumps of old trees, especially in situations where a moisture has exuded which has probably served for their food, or upon which they will feed when they regain their activity. M. Desvoidy has united the *Stomoxys* with the *Muscidae*, and has formed the *Stomoxys irritans* into the genus *Hæmatobia*.

**CONOSPERMUM** (R. Brown). New Holland ornamental ever-green shrubs, belonging to *Tetrandria monogynia*, and to the natural order *Proteaceæ*. Generic character: calyx tubular, gaping; upper segment hollow at the base; anthers three; side one halved, the upper two lobed; stigma free; nut inversely cone-shaped, crowned with rigid hairs. These plants have narrow heath or yew-like leaves, and therefore add variety to the green-house collection.

**CONOVULUS** (Lamarck; a *Volute* of Linnæus). One of its species has also been classed, by Lamarck, with the genus *Tornatella*; both of them are now, however, placed with the *Pedipes*, in the second family *Auriculaceæ*, first order *Pulmobranchiata*, second class *Paracephalophora*. The shell is thick, ovoid, sub-involved, the spire very short, the last whorl much larger than all the others united; the aperture long, oval, or linear, the edges not united, the external one sharp and thin, internally dentated; one or two decurrent plaits at the columella, one of which serves to separate the two portions of the animal's foot. The animal, according to Adanson, is known. Several fossil species are mentioned by De France, which are classed with the genus *Tornatella*.

**CONULARIA**. A fossil species of mollusc, of which the *Conularia Sowerbii* is an example; it is, however, a badly defined genus and should not be placed with the *Orthocera* of the modern school, except as being greatly similar in structure to many of its species.

**CONUS** (cone).—(Linnæus and various modern authors). Shells of this extensive and elegant genus are generally so well known to every collector, that it were needless to say their name is derived from the resemblance to a cone. The genus comprises not only the most beautiful, but also the most numerous of the class which comprehends the spiral univalves. Among them are many of high price, even at the present day, when the rarity of certain species is less than it was a few years since, from the increased researches made in this branch of natural history, and from the competition in our sale-rooms becoming less in proportion. Cones constitute a very natural and easily distinguished association of molluscs, including an almost endless number of species and varieties; but few other shells can, by possibility, be confounded with them. To a casual observer, some others, however, present a striking resemblance; the cowry (*Cypræa*), in a young state, has been mistaken for a cone, though it is then very thin, and all cones are thick and heavy, and one author, of little repute it is true, has confounded a species of the genus *Oliva* with the cones. The most remarkable and distinguishing

character of this genus is, the shell having the whorls compressed and rolled over each other, the outer one being visible, and the upper edges of the previous evolutions only seen with a suture or groove between them. These spiral elevations form the spire, which is sometimes nearly flat, convex, more or less produced, and occasionally even slightly concave; the extremity of the whorls coronated, smooth, or tuberculated. It results from the form of the shell, and the spiral cavity (which contains the animal) being compressed in its whole length, and the larger part near the spire, that they may strictly be called turbinated shells attenuated towards the base; the aperture is narrow, effuse at the base, never dentated or the axis plaited, and the outer lip smooth and sharp; it does, however, sometimes present a slightly waved appearance in certain species, particularly at the anterior extremity, which may there be called plaited obliquely. Lamarck has divided this genus into two sections, the first including the coronated cones, the second, those with a plain spire; but this genus, like other very numerous ones possessing but few variations of character, requires a more natural association of its species, as a guide to which, the peculiar structure of the spiral whorls, in addition to the more or less elongated form of the shells, might safely be adopted by the naturalist.

Lamarck and all subsequent writers have omitted some particulars tending to exhibit, more strongly, the peculiar characters of this elegant shell; the aperture is terminated, at the upper part, in a notch, more or less distinct, admitting the protrusion of an organ of the animal, and occasioned also by the suture or separation of the external whorl from the spire; beneath this appears a slight callosity, running round the interior of the shell.

The form of the shell is extremely various, some being rather thin, cylindrical, and oval, others short and wide, some with a spire very much produced, while, in others, it is nearly flat and truncated, either mucronated, coronated, tuberculated, or with flattened or convex whorls; the exterior more or less covered with minute granulations; some are quite smooth, and others transversely grooved or sulcated; all the species may be presumed to have an epidermis, which, in some, is very thick and has a tufted appearance. Adanson, whose veracity has never been impugned, asserts, that these shells are closed by a very small horny operculum sub-spiral, with a terminal summit; but of some hundred specimens of cones which have passed through our hands, no one ever has been met with by us possessing an operculum. The animal constructing this shell is of a lengthened very compressed form, rolled round like a riband wound up on its own axis; the mantle is extremely thin, not projecting beyond a rather small foot, of a lengthened oval form, larger in front, where it is bordered by a transverse groove; the head is very distinct, the tentacula cylindrical, with the eyes situated near their summits, which are setaceous; the mouth is placed at the bottom of a rather long labial trunk, the tongue is rather short, although salient in the visceral cavity, and bristled with two rows of long styliform hooks.

The following distribution of species has been made by French naturalists, and it is tolerably natural, though admitting of some reformation. The first division consists of those cones which have the form of the body regularly conical, with a projecting spire, not coronated or tuberculated, as is the case

case with the *Conus generalis*; the second, such as have a spire salient or projecting, but with its whorls *coronated*, projecting, or flat, as in the *Conus imperialis*. In these examples we may point out the reasons why we differ with such an arrangement; taking as our guide the formation of the spire, it is obvious that the animal constructing the *C. generalis* has an organised portion of its body immediately under, and upon which the spire was formed, different from that which exists in a similar position in the *C. imperialis*, where the knobs or coronated processes are so distinctly defined, and can only arise from corresponding elevations of the animal's body; on this account, therefore, we would suggest the separation of all species having a distinction so clearly marked: it cannot, it is true, in any way change the classification of the inhabitants, since they remain precisely the same in all their organs, though those organs differ in form, length, and particularly in size, it is, therefore, from the modifications of these at the posterior part of the animal's body that the spire exhibits its various characters. The substance of the animal's body, that is, its being of an uniform thickness throughout its whole length, or its being in some parts thicker than in others, constitutes the difference that exists in the *external* form of the cone, by which it is rendered more or less perfectly conical, globose, elongated, or compressed, and the peculiar manner in which the animal's flat riband-like body is rolled up distinguishes the length of the spire. This may be easily understood by the familiar illustration of a narrow roll of paper, one end of which is more or less drawn out, so if we imagine that roll to possess at one end convex portions at stated intervals, these would form the coronated or tuberculated spire; and were the roll of paper more or less convex throughout the whole of its breadth, the loosely formed cone made from it, would be rendered globose in proportion to that convexity, whether in one part of its folds, or uniformly in every part. Many cones are also granulated on their exterior, some grooved, and others variously sculptured; these variations are easily understood, as corresponding with similarly formed portions of the animal's body. See CONCHOLGY. They, we also think, should tend to point out the natural association and progressive links of the species. The third division made by the French naturalists is, that in which the species are but little elongated, more oval, the spire rather projecting, pointed, and not coronated, as in the *Conus textile*; the fourth, such species as have the spire apparently *coronated*, and the form of the body sub-cylindrical, as in the *C. geographus*; the fifth includes the species much elongated, cylindrical, a salient spire, the aperture resembling that of the genus *Terebellum*, that is, angular at its posterior portion—this is exemplified in *C. mitratus*, *C. nussatella*, and others.

In these sub-divisions it must again be pointed out that they are to be considered with reference only to the classification of the shells themselves, the animal itself always remaining one and the same species in all. It belongs to the second class *Paracephalophora*; first order *Siphonobranchiata*; third family *Angyostomata*.

Lamarck enumerates 181 recent species, more are, however, now described; they are the most abundantly found in tropical climates, and like many other molluscs become more rare as they approach the northern hemisphere, where none exist, and only

four, or perhaps five, species are to be found in the Mediterranean. Fossil remains of the genus are not uncommon, and are widely distributed, never being found in masses, as frequently occurs with other genera of molluscs.

These shells are unquestionably the most elegant of all the various known genera; their form is always graceful; they present, in their coloured portions, every possible shade, including that of green, so rarely found in other molluscs, and the diversity of marking in the different species baffles description or correct imitation.

Though it forms no part of this work, properly speaking, to point out present, or former rarities of the species of molluscs, we cannot, however, avoid trespassing upon the space allotted to our subject, by briefly pointing out some of those which, from their extreme beauty, will ever retain a marked preference. At the head of which must stand the well-named cone (*Conus cedonulli*), in all its varieties; the *C. aurisiacus*, and the varieties of the *Conus ammiralis* are, nevertheless, scarcely inferior in beauty. One species has long preserved a reputation it probably merits more from its great rarity than its extreme beauty—it is the *Conus gloria maris*, for though it is a most elegant mollusc, there are some varieties of the *Conus textile* which approximate it so closely, that we only consider it a variety of that species. We have named these cones as a few of the most rare and beautiful known, but amongst the most common numbers exist, which, if equally rare, would rival them in elegance of form, colouring, and pencilling.

In the records of conchological extravagance, it is stated that some examples of rare cones have been so strongly competed for by amateur collectors, that one hundred pounds have been given for them; it is, indeed, within our own knowledge, that twenty pounds have been paid for a fine specimen of the *cedonulli* and *aurisiacus* cones; and even at the present period they could not probably be bought under half that amount. The somewhat trite adage of a "fool and his money being soon parted," does not, however, in this instance, more particularly apply, than in a thousand others; from the earliest ages of history mankind have been often known to sacrifice, not only immense sums, but every moral duty towards their fellow creatures, to acquire possession of an object not attainable to others on the score of riches or vanity. To a certain extent, wealth must ever command an indulgence of this or any other bad passion; but, happily, the satisfaction of doing good so much preponderates, that instances of selfish extravagance are hourly becoming less conspicuous. The blind gifts of fortune are dispensed with a liberal, discriminating judgment, by those who enjoy a superfluity of them, and are blessed with minds so constituted, as to appreciate the sacred duties which rank or wealth impose upon them, by alleviating the sufferings of beings less fortunately placed in the scale of worldly enjoyment than themselves.

CONVALLARIA (Linnaeus). The *C. majalis* is a British plant, and one of the most valued of the British flora, under the name of Lily of the Valley. Linnaean class and order, *Hexandria Monogynia*; and natural order *Smilacææ*. Generic character: corolla tubular, limb six-cleft; stamens joined to the tube; filaments awl-shaped; anthers erect, and somewhat egg or heart-shaped; style columnar; stigma headed. Berry of three cells, each containing several seeds.

The simple beauty of the smooth fresh green leaves, surrounding and serving as a background to the elegant racemes of pure white nodding flowers, is a contrast which enhances the value of both. Those who are the least sensible of the beauty of flowers, appear charmed with the simple elegance of the lily of the valley. So much has it been cultivated in every garden, that two varieties have been already obtained, namely, the red flowering and the double; all of which are easily increased by division, and will thrive in any shady place.

**CONVOLVULACEÆ.** The bindweed family. A natural order of dicotyledonous plants, containing upwards of twenty genera, and between two and three hundred known species. Its plaited corolla, and climbing habit, are the characters by which this order is best distinguished from all others. It bears an affinity to *Cordiaceæ* in its shrivelled cotyledons, and it is also allied to *Polemoniaceæ* and *Hydroleaceæ*.

Its essential characters are: calyx with five divisions, persistent; corolla monopetalous, hypogynous, regular, the limb five-cleft, generally plaited and deciduous; stamens five, inserted at the bottom of the corolla, and alternate with its segments; ovary single, two to four-celled, rarely one-celled, sometimes in two or four divisions, with few definite erect ovules; style one, often divided at the apex, sometimes as far as the base; stigmas obtuse or acute; capsule one to four-celled, the valves corresponding to the angles of a free dissepiment, bearing the seeds at its base, sometimes without valves, or opening transversely; seeds with a small quantity of mucilaginous albumen; embryo curved; cotyledons wrinkled; radicle inferior.

The plants belonging to this order are herbs or shrubs, which are usually climbing, milky, smooth, or with a simple pubescence. Their leaves are alternate undivided or lobed, without stipules, and their inflorescence terminal or axillary. They have frequently showy flowers, which expand beneath the influence of bright sunshine. They are found twining round other plants, or creeping among weeds on the sea-shore in the tropical regions of the globe, and are by no means abundant in cold climates. Their roots abound in an acrid milky resinous juice, possessing purgative qualities. Some of them are employed as articles of food.

The chief genera of the order are, *Convolvulus*, *Calystegia*, *Ipomœa*, *Cuscuta*, *Evolvulus*, *Argyrea*, *Falkia*, and *Reticia*.

*Convolvulus*, bindweed, is a very extensive genus, and includes some species which are prized on account of their beauty, or the valuable products which they furnish.

*Convolvulus*, or *Ipomœa jalapa*, is a climbing perennial plant, found near Xalappa, a town of Mexico. It was first brought to Europe in 1610. The root of the plant furnishes the medicinal jalap. It is a tuberous egg-shaped root, which, when fresh, is white and lactescent, but, as imported, is generally covered with a blackish wrinkled bark. It is sometimes brought to this country in the form of thin transverse slices, having a greyish colour internally. The tubers, when sound, are compact, hard, and heavy, and break with a resinous fracture. They have a nauseous taste and smell, and seldom exceed a few ounces in weight, with a diameter of two or three inches. When powdered, jalap has a yellowish grey colour.

The roots of common bryony, the marvel of Peru (*Mirabilis jalapa*), and of other species of convolvulus, are often mixed with those of the true jalap.

Jalap has been ascertained by analysis to consist of resin, extractive matter, starch, vegetable albumen, woody fibre, and various salts. A substance has lately been obtained from jalap possessing powerful purgative properties, and which, from being considered its active principle, has been denominated *Jalapine*. The observations made in regard to it however, are not as yet satisfactory.

The properties of jalap reside chiefly in the resin. When administered in small doses, of ten or fifteen grains, this medicine is an effectual, safe, and mild purgative; but when given in large doses it produces griping, watery, evacuations, and may even excite inflammatory action. Camphor is one of the best substances for preventing its griping effects. It is frequently prescribed in combination with calomel and cream of tartar. When mixed with two parts of the latter salt, it constitutes the compound jalap powder of the Edinburgh Pharmacopœia.

The watery extract of jalap possesses the properties of the root in a weak degree. The resin, by itself, produces distressing symptoms, without much effect in evacuating the bowels. Diluted alcohol, or proof spirit, dissolves almost all the active ingredients of jalap.

The root of *Convolvulus panduratus* is used in the United States as a substitute for jalap.

*Convolvulus scammonia* (scammony), is another climbing species of bindweed, found in the Levant, Syria, and Turkey, and growing abundantly on the mountains between Aleppo and Latakia. The roots of this plant are three or four feet long, and nine or twelve inches in circumference, and when cut yield a milky juice, which concretes, and forms the gum-resin known in medicine by the name of scammony. The following is the mode in which the gum-resin is collected:—The earth being removed from the upper part of the root about the month of June, an incision is made obliquely across it, and the milky juice which exudes is allowed to flow into a shell or cup placed at the lower end of the cut. After the vessel has been left for twelve hours, it is removed, and the concrete juice is taken out. Each root yields only a few drachms. The produce of several roots is then collected, and put into packages or drums, as they are called, which weigh from 75 to 125 pounds. The best scammony is brought from Aleppo. An inferior sort is exported from Smyrna in the form of cakes, like wax, packed in chests. This would appear to be the produce of another plant, *Periploca scammonium*.

Scammony is frequently adulterated with sand, ashes, and the juice of other plants, such as *cynanchum*, *monseliacum*, &c. The Smyrna scammony is said to be sometimes an entirely artificial compound, containing no real scammony whatever.

Pure Aleppo scammony occurs in the form of light, spongy, friable masses, having a heavy disagreeable smell, a bitter acrid taste, and a blackish or dark grey colour. When broken, it exhibits a smooth somewhat shining fracture, and when powdered is of a light grey, or whitish colour. Scammony consists of resin, gum, and extractive matter. It possesses powerful purgative qualities, which reside in the resin, of which it is chiefly composed. It is administered in doses of five or ten grains, and is frequently prescribed in combination with calomel,

jalap, cream of tartar, and sulphate of potass. It is sometimes triturated with sugar or almonds, and is then said to be mild in its operation. It is often used in cases of dropsy and worms.

Both scammony and jalap, when rubbed externally on the skin, produce purgative effects.

*Convolvulus arvensis*, small bindweed, is common in corn-fields and by the sides of hedges in Britain. Its flowers are small and rose-coloured, and it has a white-jointed root, which runs deep into the ground, and is difficult of extirpation. It twines round wheat and other kinds of grain, and is a troublesome weed in cultivated grounds. Its presence is said to indicate in general a dry soil. Its juice is slightly purgative, and its blossoms give to water a deep yellow colour, which is increased by the addition of alum and alkaline substances.

*Convolvulus*; or *Calystegia sepium*, great bindweed, is another indigenous species, which is much larger than the preceding, and produces showy white flowers. The inspissated juice, in doses of twenty or thirty grains, is said to be purgative.

*Convolvulus*, or *Calystegia Soldanella*, sea-side bindweed, is the only other British species. It is common on sandy places by the sea-shore. Its root is long and creeping, and its flowers few, large, and rose-coloured.

*Convolvulus batatas*, skirrets of Peru, Spanish potatoes, or the common sweet potato of Europe, is a native of the East and West Indies and of China. It was first brought to Spain from the West Indies, and its root used to be imported into this country as an article of food. Its root is the potato of Shakspeare, and the writers of his day, at which time our present potato (*Solanum tuberosum*) was scarcely known in Europe. In tropical countries it is still cultivated like the potato. Not only its tubers, but also its young leaves and shoots, are boiled and eaten. The root of *Convolvulus edulis* is also frequently used as food.

The roots of *Convolvulus floridus* and *scoparius* produce sneezing. The wood of the latter species, which grows in the Canary Islands, is remarkable for its fine rose-like odour. *Convolvulus repens* is employed as a pot-herb in the East Indies and China. *Convolvulus turpethum* (*turbith* or *turpeth*), is a native of the East Indies, and furnishes a root which has been used medicinally as a cathartic. A resinous matter is obtained from it. *Convolvulus Malabaricus*, a native of the Malabar coast and Cochin-China, is considered in India a valuable horse-medicine. The genus *Ipomæa* consists of twining stove plants, which are easily cultivated, and flower very readily. Upwards of one hundred species are described by botanists. They are remarkable for the beauty of their flowers, which, though they are individually short-lived, yet they are succeeded so rapidly by others, that there are few more showy ornaments of the forests in warm countries, or of stoves in our own. *Ipomæa tuberosa* is a plant of great beauty and fragrance. In Jamaica it is evergreen. It is thickly covered with leaves and large flowers, and is a beautiful ornament of arbours. It yields a milky juice, which, when concrete, resembles scammony. *Ipomæa inamoclit* is a beautiful annual. Its root is used as a sternutatory.

*Cuscuta*—dodder, a genus of leafless plants, which, after germinating in the ground and deriving nourishment from it, become parasitical, and attach them-

selves to some plants in the neighbourhood. Their stalks twine round these plants, contrary to the sun's apparent motion, or from right to left, sending out from their inner sides little papillæ or tubercles, which attach themselves to the bark of the supporting plant, and finally become firmly and intimately united with it. They then derive their support and nourishment from the plant to which they become attached.

*Cuscuta Europæa*, great dodder, is found in Britain on nettles, flax, &c., and produces flowers of a pale yellowish rose-colour. *Cuscuta epithymum*, lesser dodder, another British species, is found on furze, heath, and thyme. It is distinguished from the preceding species by having a scale at the base of each stamen.

CONVOLVULUS (Linnæus), is the very significant generic name of all that family of plants called bindweed. They belong to the fifth class and first order of Linnæus, and, as we have already stated in the previous article, give a title to an order in the natural system. This genus is spread over every part of the known world, and appears in every degree of bulk and beauty, and of every grade as to duration; some are annuals which embellish our flower borders for a few months, and then disappear; some are biennials, but the great majority are perennials. They are nearly all either creepers, twiners, or climbers; many are troublesome weeds, though the flowers of all are showy. They are all easy of cultivation, and thrive in almost any kind of soil. This genus, though still very numerous, was formerly much more so, many of the species having been separated, and added to the two congeneric genera of *Ipomæa* and *Calystegia*.

CONYZA (Linnæus). A genus of shrubs and herbaceous plants found in many and distant parts of the world, and known by the common name of fleabane. Linnæan class and order *Syngenesia superflua*, and natural order *Compositæ*. Generic character: anthodium scaly; receptacle naked; florets of the ray trifid, or somewhat two-lipped. The fleabane is a British biennial of no great beauty; the foreign are mostly of like character. Some of the shrubby species are kept in greenhouses, where they are easily increased by cuttings treated in the usual way.

COOKIA (Sonnerat). A genus of fruit tree indigenous to China and the neighbouring countries, and called by the natives wampee. Linnæan class and order *Dicandria monogynia*, and natural order *Aurantiaceæ*. Generic characters: calyx in five parts; petals five, white, and villous; stamens filaments linear; anthers roundish, apple imperfectly two-celled, one seed in each. The tree has been long in our collections, and grows well in a large pot, in loamy soil. From what we have experienced of other Chinese plants, such as the tea-plant, camellia, and others, it may be expected that the wampee may bear our winters if planted against a south wall, and be allowed sufficient protection against frost.

COOT. See FULICA.

COPPER. The mineralised ores of this metal are very numerous, and it is found in a native state in many parts of the world. Native copper occurs in a variety of forms, massive, dendritic, granular, and crystallised in cubes, octohedra, &c. This mineral is accompanied by several other substances, as the ores of zinc, and occasionally of lead; sometimes of tin, silver, and arsenic, with quartz and fluete of lime, and calcareous spar in abundance. It is met with in Cornwall, the Hartz, Saxony, Sweden, and

in America; but the native coppers of Japan and Brazil are usually alloyed by gold. It is commonly accompanied by quartz, heavy spar, and calcareous spar, except in Cornwall. Mineralised by a certain proportion of oxygen, it forms a beautiful mineral, called the red oxide of copper, which assumes a great variety of forms, all of which may be traced into the regular octahedra; but with an increased proportion of oxygen, it assumes a black hue, and is mostly pulverulent.

The foliated and compact red copper ore occurs in different veins in the mine of Huel Gorland, in Cornwall. All the veins traverse granite, and three of them, viz. the North Lode, the Great Gossan Lode, and the Muttrel Lode, afford the red copper ore. In the North Lode it is associated with fluor spar. In the Great Gossan Lode it occurs in considerable quantity, and is occasionally intermixed with native copper; higher up in the same vein there is abundance of fluor spar, sometimes intermixed with arsenical pyrites, and copper pyrites. In the Muttrel Lode the copper ore is occasionally accompanied with copper glance, or vitreous copper ore, black oxide of copper, olivenite, arsenical pyrites, quartz, and fluor spar. It is also found in several other mines. Small portions of this ore occurs, along with native copper, in the trap-rocks of Nalaoe, one of the Faroe Islands; also in the mine of Aardal in Norway, and Garpa in East Gothland, in Sweden. It occurs but sparingly, and along with native copper, in the Kemmelsberg, in the Hartz; near Freyberg, along with native copper, ochry-brown iron ore, lamellar, heavy spar, and quartz. In Asia this ore of copper occurs in the Uralian chain of mountains, and also in the mines of Kolywan. In America it is principally found in Chili and Peru. Both the blue and green carbonate of copper are found in a native state, the latter under the name of MALACHITE, which see.

**COPRIS** (Geoffroy). A very extensive genus of coleopterous insects belong to the section *Pentamera*, and sub-section *Lamellicornes*, and family *Scarabidæ*, having the body large and thick; the antennæ terminated by a three-jointed fan-like club; the head and thorax often armed with powerful horns, especially in the males; the scutellum appears entirely wanting, and the four posterior tibiae are strongly dilated and obliquely truncate at the extremity. The Count De Jean enumerates eighty-four species of this genus, which are for the most part inhabitants of the warmer quarters of the globe, especially frequenting Africa and the East Indies, where they are important agents in the economy of nature, the eggs being buried in the excrement of various animals, within which the larvæ feed and the beetles are perfected. The species which we have figured in our plate of beetles, from the collection of the Rev. F. W. Hope, is the *Copris isidis* of Savigny, one of the largest insects in the genus, of a black colour (as indeed are all the species), with reddish hairs in front of the thorax; it is from Egypt. There is only one British species, the *Scarabæus lunaris* of Linnæus (the *Scarabæus emarginatus* of Fabricius being merely the female). It is of a black colour, with the single upright horn in the middle of the head in the male. It is nearly an inch long, and may be occasionally found emerging from holes made in the ground beneath cow-dung, and taking flight towards sunset.

**CORALLIFERA**, a numerous order of marine animals belonging to the class *POLYPI*, which see.

**CORDIACEÆ**. A natural order of dicotyledonous plants, containing six or eight genera, and upwards of fifty species. It is closely allied to *Boraginæ*, and by many authors is looked upon as a section of that order. It is distinguished, however, by its general habit, its plaited cotyledons and dichotomous style. It bears an affinity also to *Convolvulaceæ*, from which it differs in its inverted embryo and drupaceous fruit.

The essential characters of the order are: calyx inferior, five-toothed; corolla monopetalous, with the limb in five divisions; stamens alternate with the segments of the corolla, out of which they arise; ovary superior, four-celled, with a pendulous ovule in each cell; fruit a four-celled drupe; embryo inverted; cotyledons plaited or shrivelled longitudinally; seeds without albumen.

The plants belonging to the order are trees with panicle, bracteate flowers, and alternate rough leaves without stipules. They are found in tropical regions in both hemispheres.

They generally yield emollient and mucilaginous fruit, but little is known in regard to their properties.

The chief genera of the order are: *Cordia*, *Varronia*, *Geraschanthus*, *Cerdana*, *Cordiopsis*, and *Menas*.

*Cordia myxa* is a large tree, growing in the East Indies, and yielding a yellow-coloured fruit the size of a cherry, which is eaten by the natives. The bark of the tree is tonic, and is used in Java in cases of fever. Its wood is tough and solid, and is employed to procure fire by friction. The leaves are bruised with those of *Datura metel*, and applied to the forehead in headach. A kind of glue is prepared from the fruit.

*Cordia sebestena* is a very ornamental tree, on account of its large tubular scarlet flowers. Its wood is odoriferous when burnt; a small bit of it put on a pan of heated coals will perfume a whole house. From the juice of the leaves, with that of a species of fig, the inhabitants of Otaheite procure a fine red colour, with which they dye their cloths. The fruit of this and the last-mentioned species are commonly known by the name of sebesten plums. These are occasionally brought to Europe in a dried state, and their pulp is said to act as a laxative.

*Cordia alliodora* is called in India clammy cherry or Turkey berry tree. Its leaves are used in that country to feed poultry.

**CORIARIEÆ**. A natural order of dicotyledonous plants, containing only one known genus and seven species. It is allied to *Ochnaceæ*, but differs in having no style, and in its stigmata being long, linear and distinct. It also resembles *Rutaceæ*, the rue family, and has some affinity with *Connaraceæ*. The essential characters of the order are: flowers either hermaphrodite, monœcious or diœcious; calyx five partite; petals five, fleshy, with an elevated keel in the inside; stamens ten, of which five arise between the lobes of the calyx and angles of the ovary, and other five between the petals and the furrows of the ovary; filaments thread like; anthers oblong, two-celled; ovary on a fleshy disc, five-angled and five-celled; no style; five long awl-shaped stigmas; five carpels which are one-seeded, and close together when ripe; seed pendulous, without albumen; embryo straight; radicle superior; cotyledons fleshy.

The plants belonging to this order are: shrubs with opposite square branches, opposite entire leaves, scaly buds, and terminal racemes, which are leafy at the base. They are found in various parts of the

world ; in the south of Europe, in Peru, New Zealand, and Mexico.

*Coriaria* is the only genus of the order.

*Coriaria myrtifolia* grows in hedges, and thickest in the southern parts of Europe, and in the north of Africa. Its leaves and young branches are astringent, and are used in dyeing black and in tanning. The plant yields a poisonous fruit, which has proved fatal on some occasions. Several soldiers of the French army, in Catalonia, were stupefied by eating it, and some died from its effects.

Its leaves are said to be sometimes mixed with those of senna. According to M. Guibourt, this adulteration is detected by the infusion with hot water, having a pale yellow colour and astringent taste, by a white precipitate being thrown down by gelatin, a blue by sulphate of iron, a black by nitrate of silver and nitro-muriate of gold, and a gelatinous compound by caustic potass.

**CORMORANT** (*Phalacrocorax*), a genus of sea-birds belonging to the family of *Totipalmæ*, or those which have the hind toe included in the web of the foot, as well as the three front ones. The structure and action of a foot of this kind will be found noticed in the article **BIRD** ; so that we need not repeat it here. In their general characters, this genus is nearly allied to the pelicans, and were included in the same genus by Linnæus and his followers ; but Cuvier has very properly separated them, as they are so different both in structure and in their general economy, that the same description will not apply to them, and when that is the case there ought always to be a separation of genera.

Cormorants are sometimes called sea ravens, or sea crows, and they have nearly the same voracity as the land ravens, though their prey and manner of catching it are both very different. Cormorants generally fish near the shores, and are more frequently on the wing over the water than at rest upon the rocks. When they pursue their prey in the sea, they do not hesitate in coming near inhabited places ; but when they fish in the fresh waters they choose more lonely haunts. They catch their prey, which consists wholly or chiefly of fish, by the middle with the bill ; and as they cannot easily swallow it from this position, or indeed if it is presented to the gullet in any other way than head foremost, they throw it into the air and seize it with great dexterity as it falls. All birds which fish along the surface of the water, and indeed all animals which swallow their prey without masticating or dividing it with the teeth, are dexterous at this mode of turning a fish.

This is one of the most remarkable instances of adaptation with which we meet in nature ; and ought to teach us to look for the intelligence of the creature somewhere else than in the creature itself, is the fact that the action performed in this perfect manner by the organised animal is not the result of the organisation, neither is the organisation the result of the action. A cormorant does not catch fish by dashing into the water, and following them to a greater or less depth, as may be necessary, *because* its feet, its wings, its bill, and all the other parts of its organisation are fitted for such purposes, any more than it throws the fish up into the air, because it has a knowledge that the fish will come down in a more manageable posture for swallowing than that in which it is seized by the bill. As little can we say that the bill has or can have any controul

over what its organisation shall be, for the organisation precedes the action in the order of nature. The instinct follows the race, and is true to it ; which we find is not the case either in knowledge or in action with us. Therefore, when we examine the more curious functions which are performed by the lower animals (as we term them), we meet with far more striking evidences of Almighty wisdom and power than we do in the case of human conduct. There are no productions which assist us more in the forming of these general views than those birds which seek their food in the waters ; and as the cormorants find their food by skill and energy, not by craft, there are few sea birds better worthy our attention.

Cormorant.

The characters of the genus are as follows :—The bill long, or of mean length, compressed, rounded in the culmen, straight for the greater part of its length, but much hooked at the tip of the upper mandible, and having the extremity of the lower one truncated, so as to act against the hook. The base of the bill has a small cere, and the naked skin is continued on the throat, and partially also on the face. The nostrils are at the brow of the bill, in the form of longitudinal slits, and barely visible. The legs are stout, the tarsi short, and rather inclined toward each other. The hind toes are turned inward, and included in the web of the feet ; the outer toe is the longest and strongest in the foot ; the claws are not large for the size of the foot, and that on the middle toe is toothed on the edge. The wings are of rather more than mean length, and they are rather pointed, the second quill being the longest. They are not, however, formed for whirling and turning rapidly in the air ; and the rounded extremity of the tail further shows, that whirling in the air is not one of the principal actions of the bird. There are several species :—

*P. carbo*, the common cormorant, or great cormorant. This species is common on the British shores, and in some places it moves inland to the lakes which are near the sea, or to the larger rivers, which have long tideways. In these last situations, it is often

found standing or nestling on trees; but as a sea-bird, its place of repose and nestling is the rocks.

This is a large bird: three feet in length, nearly five feet in the extent of the wings, and weighing as much as seven pounds; but this must be considered as the dimensions of a large specimen, and the sizes are apt to vary. Length of the bill about five inches, and of a dusky colour for the greater part of its length, but with the cere yellow; tarsi, toes, and webs sooty black; irides bright green. The plumage varies a little with the season. General colour, greenish black, with black margins to the feathers on the back, and a line of ash colour on the scapulars. In the breeding season, the neck and thighs are mottled with small white feathers, and there is a crest of long green feathers on the back of the head. In winter these feathers fall off, and the general tint of the upper part becomes rusty. There is also a white gorget on the neck, which becomes much duller in the colour during winter.

Though these birds are generally found in remote and inaccessible places for their nests, such as high trees and detached rocks, they are social with each other, and many nests are often found in the near vicinity of each other. The eggs are three or four in number, of about two ounces in weight, greenish white, and with the surface of the shell rather rough.

Though cormorants are industrious and successful fishers, and as such thin the waters of their finny inhabitants to a considerable extent, yet they pursue their fishing with peace and good order, and never interfere with or annoy any other birds. It can be tamed very readily; and a detailed account of one in a domesticated state may be found in Montagu's Ornithological Dictionary.

The common cormorant extends to the very coldest parts of the northern hemisphere, being found in Greenland. Wherever, indeed, there is an open sea, and high rocks to afford the resting place which the birds most affect, there is never any want of cormorants, though in such places they are forced to shift their quarters with the season. They are driven not merely by being frozen out, but by the unusual departure from the coast of those fish on which they feed; so that, if the movements of cormorants and other fishing birds were properly attended to, it would throw very considerable light, not only on the natural history of the inhabitants of the waters, but on the seasons at which fishing for the different kinds of the finny race can be carried on with the greatest success, and where every species should be sought for, when it disappears from any particular spot. All oviparous fishes, and they comprise the kinds which are most valuable to man as food, spawn on the banks or shores, or in the estuaries of rivers; and the young remain for a considerable time near the shore before they betake themselves to the deep water. Much of the spawn is detached and brought to the surface, or washed to the water line on the shore, where it forms a very considerable part of the food of terns and other skimming birds, and also of those birds which pick up their food, by running along the sands. Therefore, we find these birds on the shore, and in the full activity of breeding and nest building where the spawn is deposited. Cormorants and other fishing birds come later, after the fry have attained a considerable size, and their breeding time comes on when the numbers and size of the young fish on the coast are a maximum as taken together. When the spawn is gone,

and the young fishes have attained considerable size, the skimming birds which, by this time, have reared their broods, find it necessary to disperse themselves over the ocean. The fishing birds, properly so called, have then the shores in a great measure to themselves, and, as the weather suits, they may be seen driving about with great activity. But their time for dispersing comes in the end, and they scatter more widely along the shores than the skimmers, as they are larger birds, and individually consume more food; and it is on such occasions as this that the cormorants, which are perhaps the most voracious of the whole, betake themselves to the fresh waters, though, where these waters are large, and abound with fish, cormorants, sometimes choose their breeding places on the trees near such waters, in the manner that has been described already. When they nestle on the rocks, or even when, on trees, they do not, as is the case with many other birds, return to the same rocks, but shift about from one to another.

When they are not employed in fishing, and especially when they have fished to the full expansion of their wide and swelling stomachs, they sit down in a state of very dismal repose, and at other times they may be seen by dozens together, drying themselves on the rocks, with their wings spread out as flat and as motionless as if they were dead carcases which had been placed there by human art.

As food, the cormorant, though a large bird, is of little or no value; the smell of it is very rank and offensive, and the flesh, dressed in any of the common ways, would suffice to turn the stomach of a Greenland or an Esquimaux. But, in some of the northern islands, the young are eaten, and even relished as a sort of dainty, after having been buried for twenty-four hours in the earth, which is said to remove the bad flavour of the flesh, and also to make it tender. Soup made of them in this manner is said to taste *something* like hare-soup; but we should be a little sceptical of the fact, though good soup may be made with *any* thing in it as *one* ingredient, which is not of so positively offensive a nature as to spoil the rest.

When regal amusements consisted more of field sports than they do in these days, there was an office of the royal household of England, known by the style and title of "Master of the King's Cormorants." Whether such an office may not still exist, and be exercised under another name, is not a point which writers on natural history are called upon to settle; but it is certain that, in those comparatively rude and primitive times, cormorants were trained to catch fish, and prevented from swallowing what they did catch by a tight collar of leather put round the neck. They were not difficult to train, were expert in their labour, and docile and easily managed.

*P. graculus* (the Shag, smaller cormorant, or smaller sea-crow). This species is much smaller than the former, and it is also more lightly made, and more active, found at more places of the coast, and more constantly there. The action of the shag upon the water, on a fine breezy day, when the smaller fishes are near the surface, is very amusing, and even graceful. It floats with wonderful buoyancy in the air, twitches down to the water with the rapidity of lightning, and sometimes passes clean through the unbroken surge, and appears upon the wing on the other side.

The shag is subject to considerable varieties in size; and, as the young are without the crest, and

the old ones lose it in winter, we generally find the shag and the crested shag described in the books as different species. There is, however, every probability that they are the same.

Besides size and colour, the most remarkable difference between the shag and the cormorant consists in the number of feathers in the tail, which are only twelve in the shag, and fourteen in the cormorant. The tail of the shag is also larger, more wedge-shaped in the general outline of the end; it is also more graduated (*étagée*), that is, the ends of the feathers appear like a succession of steps, as they do in the tail of the magpie. The size, as we have said, varies, but the longest of them that have been measured is about two feet six inches in length, three feet eight inches in extent of wing, and weighs nearly four pounds. The shag is very abundant in the regions of the arctic circles, and is a bird of passage in the eastern countries of Europe. It has much the appearance and manners of the preceding, although the two species are not observed to consort. But they are alike greedy and voracious, and after having overgorged themselves, they are often found on shore in a drowsy and torpid state; but when the torpor is over, they appear again on the water, where they are extremely alert, and not easily shot, as they dive the moment that they perceive the flash of a gun, and take care afterwards to keep out of its reach. In swimming they carry their head very erect, while the body seems nearly submerged. From the circumstance of their feathers being not quite impervious to water, they do not remain on that element very long at a time, but are frequently seen flying about, or sitting on the shore, flapping the moisture from their wings, or keeping them for some time expanded, to dry in the sun and the wind. They nestle in the clefts of rocks, or in trees, the female laying two or three whitish eggs, much elongated, and of nearly equal dimensions at both ends.

*P. Sinensis* (the Chinese Cormorant). The tail of this species consists of twelve feathers, like that of the shag, and it is described as being intermediate between that bird and the common cormorant. It is blackish brown on the upper part, whitish, and spotted with brown, beneath, and the throat white. The irides are blue, the bill yellow, and the feet blackish. This is the *Leut-ze* of the Chinese, who instruct it in the art of supplying its owner with fish. On a large lake, Sir George Staunton and his party saw thousands of small boats and rafts, on each of which were ten or a dozen of these birds, which, at a signal from the owner, plunged into the water, and returned with fish of a large size. They appeared to be so well trained, that it did not require either ring or cord about their throats to prevent them from swallowing any portion of their prey, except what the master was pleased to return to them for encouragement and food.

There are many species or varieties of cormorants in different parts of the world, especially in the south, but their habits are everywhere nearly the same.

**CORNEÆ**—The cornel family. A natural order of dicotyledonous plants, containing five genera and twenty-six known species. It is closely allied to *Caprifoliaceæ*, and is by many botanists considered as belonging to one of the sections of that order. It differs, however, in its valvate aestivation, the number of its stamens, its single style, its drupaceous fruit, and its fleshy albumen. By the same characters it is dis-

tinguished from the order *Hamamelidææ*, to which also it bears an affinity.

Its essential characters are: tube of the calyx adnate with the ovary, limb four-lobed; petals four, oblong, broad at the base, inserted on the top of the tube of the calyx, regular, with a valvate aestivation; stamens four, inserted along with the petals, and alternate with them; anthers ovato-oblong, two-celled; style filiform; stigma simple; drupe baccate, crowned with the limb of the calyx; seed pendulous and solitary; albumen fleshy.

The plants belonging to the order are: trees or shrubs, rarely herbs, with opposite, entire or toothed leaves, and capitate, umbellate, or corymbose flowers. They are found both in the cold and warm regions of Europe, Asia, and America.

The genera of the order are: *Cornus*, *Aucuba*, &c.

*Cornus sanguinea*, wild cornel tree, dogwood, grows commonly in Europe and in the northern parts of Asia. It is likewise found native in Britain. It bears greenish white flowers having an unpleasant smell. Its berries are of a dark purple colour, and like every other part of the plant are very bitter. An oil has been obtained from them which has been used for lamps. The bark of the older branches is dark-red, and the leaves assume this colour before they fall. The wood is hard, and makes good mill-cogs, bobbins for lace, tooth-picks, &c. It also furnishes excellent charcoal which is used in the preparation of gunpowder.

*Cornus florida*, American or Virginian dogwood, generally attains the height of twenty feet, with a diameter of four or five inches. The flowers are small, of a yellowish colour, and are surrounded by a large involucre, composed of four white floral leaves. This involucre constitutes all the beauty of the flowers. The wood of the tree is hard, compact and heavy, and is susceptible of a fine polish. It is used by carpenters. The inner bark of this and another species, *Cornus sericea*, is bitter, and is often used in North America as a tonic. In the United States, these barks are frequently prescribed for the cure of intermittent fevers. The young branches of the former species, when stripped of their bark, and rubbed with their ends against the teeth, render them extremely white. A good scarlet colour is obtained from the bark of the more fibrous roots.

*Cornus Suecica*, dwarf-cornel, is found in Europe, the northern regions of Asia, Kamtschatka, Greenland, Lapland, and North America. It is also met with abundantly in mountainous pastures in Scotland and the North of England. It is a herbaceous plant, from four to six inches high, bearing an umbel of dark purple flowers. Its fruit has a red colour and a sweetish taste, and is used in the Highlands to create an appetite. The other genera of this order do not require to be particularly noticed.

**CORVUS** (Crow, or perhaps, in the more extended sense, *Corvidæ*, the crow family), a very numerous, widely extended, and well-known tribe of birds, belonging to Cuvier's cinorostral division of *Passeres*, and in the natural classification, or that which is founded upon the general habit in feeding, and not the mere structure of the feeding apparatus, to the order of *Omnivora*, or birds which are indiscriminate in their food, subsisting upon animal or vegetable matter, recent or putrid, according to circumstances, and thus being fitted for inhabiting almost every latitude on the face of the earth.

The general characters are : the bill short, more or less compressed or flattened on the sides, sharp and trenchant in the cutting edges, slightly curved towards the point, stout in its whole structure, and, though not a tearing instrument, like the beaks of birds of prey, generally very efficient both as a thrusting and a cutting one; the nostrils are at the base of the bill, of an oval form, open, and defended by bristly hairs or stiff feathers, which project a little way forward over the base of the bill; the feet have four toes, three directed to the front, the middle one shorter than the tarsus, the whole three divided to their bases, and one toe behind. The tarsi and toes are in general stout, and in some of the species they are provided with powerful claws, which are crooked, and serve for seizing and wounding their prey. The wings are in general long and pointed; the second and third quills are, however, shorter than the fourth one, so that the wings are not of that form which is best adapted for turning readily in the air, and preying on the wing in that element.

Cuvier, following the general organisation, both external and internal, was induced to include in the crow family three races of birds, the crows properly so called, the birds of paradise, and the rollers. Some account of the second of these will be found in the article BIRD OF PARADISE, and we shall give some notice of the last in the article ROLLER; so that the present article will be restricted to the crows properly so called, though strict systematists divide them into several genera, more certainly than are required for popular services, and probably more than strict science would warrant.

There is no question that Cuvier's union of the three races which have been mentioned into one group is warranted by the general organisation; and it is equally true, that those who form arrangements upon external differences, without any regard whether these differences go farther than the mere surface or not, may make many subdivisions of a race so numerous, so widely distributed, and subjected to so many differences of food and climate as the crows unquestionably are. But, if we are to view the productions of nature in a popular sense, that is, in that sense in which they are calculated, with the least labour on our part, to throw light upon the natural usefulness of each other, we must adopt something like a middle course, so as neither to group too largely, nor to subdivide too minutely. Now, when we look at the three great divisions of which Cuvier forms the group, we find that each of them has, as it were, a different place in nature, is regulated by; or under, the controul of circumstances different from those which regulate the others, although we cannot always say distinctly what those circumstances are, or how they operate.

We find, however, that the birds of paradise are confined to a very peculiar situation on the globe, namely, the isles to the south-east of Asia, which have their climate, their seasons, and the greater part of their natural productions, peculiar to themselves, and not to be met with in any other part of the world. The rollers are not so confined or peculiar in their geographical distribution, but still they are found only in temperate latitudes, and in places which are well wooded and rich. Neither of them is, therefore, a race of birds which we can take along with us in our general tour of the world, or rather, which we do not need to take along with us, as in one or another

of their species we find them in every clime which we can visit. They are in the extreme north, in the middle latitudes, and also in the extreme south, and they are thus generally distributed always in proportion as they are more decidedly typical of the order. It is possible for a European to go where he can claim acquaintance with hardly one vegetable production, with few mammalia, few birds, and few fishes, and even where his own species seems, in appearance, in language, and in manners, more strange to him than any other inhabitant of the earth, even where the greater part are comparatively new. But a crow, and especially a raven, is instantly recognised as an acquaintance wherever it is met with, so that its appearance puts man in mind of his home, even though it is at the Antipodes; and, if there were no other charm about the birds than this universal memory which they afford, it would be sufficient to recommend them to our grateful notice and our careful study.

Generally speaking, the genus *Corvus* are all sober, and even sombre in their attire, but there are a few exceptions; and even in the most dull garbed ones there is a beautiful compactness in the plumage. Their feathers appear to be better tempered to the elements than those of almost any birds, and thus they are enabled to keep very constantly stirring and beating about on the wing; so that, though many of them are remarkably social in their habits, firmly attached to the same places, and returners to their habitual dwellings every night, yet, taking them altogether, they range more in search of their food than almost any other birds; and, as they are more generally distributed over the globe than most birds, so they are more spread over individual countries, notwithstanding that there is a certain kind of locality which each species appears to prefer to every other.

It is not a very easy matter to judge of the relative degrees of what we call sagacity or wisdom in birds, neither is it very easy to speak upon the subject without some chance of falling into error, because the inexperienced animal is just about as wise as the experienced one, and thus their wisdom, or whatever else we may call it, has a different origin, and is of a different nature, from that which is accounted wisdom in us. But still we cannot help comparing the degrees of this animal's sagacity as they display themselves in different animals; and it is not the less valuable to make these comparisons, that we do not know the nature and origin of that which we thus compare. The fact is, that this comparison of one degree with another, without any primary standard, is far more general than its opposite. When we say degrees of heat, of light, of moisture, of growth, or even of magnitude, we do not speak in terms of an absolute standard—we merely mention observed differences; and if we do this in the case of mere physical existence and its attributes, we cannot reasonably hope to be better informed, and more at home, when not merely life, but the degree of sagacity connected with life, is the subject of inquiry. Estimating them in this way, we may say, with no small degree of confidence, that the crow tribe are the most intelligent of birds; and when we consider that they are, in one or other of their species, cast upon the world generally for their means of support, instead of being confined to those places where a peculiar food for them is produced, we

might expect them to be possessed of this kind of sagacity.

Great acuteness of senses, and what, as compared with birds which are made for one place only, we may consider as remarkable habits of attention and observation, are necessary for this purpose; and accordingly, we find that these are possessed to an extent of which we have very few instances in birds, and of which it is not very easy for us sometimes to discover the use. There is certainly a perception of brilliancy of colour in these birds, and they make an election between substance and substance upon this principle alone, for which it is difficult to account upon any notion that we have of the supplying of their animal wants. Thus, for instance, if there are two little pieces of potter's ware, of the same size, shape, and consistency, and if the one side of them, as is often the case in coarse brown ware, be white and glazed, and the other not, if they are left in a magpie's way, one with the glazed side upward, and the other with the unglazed, the chance is, that the magpie will carry off the glazed and shining one, but certainly not the other; so also, if a shilling and a halfpenny are left in the way of the same bird, the shilling will likely be carried off, and the halfpenny left. If we were to argue this last election upon the principle of experience, or cause and effect, as those principles regulate our conduct, we should be apt to conclude that the magpie is not only fond of money, but a judge of the value of it. This cannot, however, be the case, inasmuch as, in times of her greatest famine, the magpie never thinks of fetching from her store of cash, or other valuables, wherewithal to purchase food, but beats the bushes with the same assiduity as if her coffers were empty.

The fact is, that those birds have a very strong habit of what we must call not merely observation, but curiosity in observation—a means, though it is impossible for us to say in what it consists, of judging of the appearance of things, and selecting one in preference to another on account of appearance only, and without any reference to intermediate usefulness in the supplying of any present want. Wild or tame, we find that animals of this family are always prying about, and that they not only perceive what is immediately beside them, but have no inconsiderable degree of knowledge of what is going on in the world around them; and though this vigilance renders them very wary of real danger, and very expert in the avoiding of it, it gives them a degree of self-possession much greater than that of most birds, and this seems to be one of the principal grounds upon which the whole race are so much more easily tamed, than from their cautious and wary dispositions we might be led to expect. In the case of most birds we require arts of taming, and in many the birds cannot be kept without the confinement of cages; but in the case of almost any species of this genus, we have only to feed them well, and they not only feel at home, but tender us their services in doing what they can to drive off other intruders.

Another remarkable quality of this, and some of the allied genera, is the great readiness with which they can be made to articulate, that is, to imitate the sounds of the human voice. This is so well known, that many people keep the birds in consequence of the habit they have acquired of repeating words; and a foolish piece of ignorance is sometimes productive of a good deal of cruelty in this particular

case. It is a vulgar belief, that they speak more plainly when their tongues are split, and much pain and annoyance is often occasioned to them by the performing of this operation. Now, there cannot be a piece of more gratuitous cruelty; for every one who knows anything about the structure of birds is perfectly aware that their tongues have nothing to do in the production or the modulation of those sounds which they utter, whether natural or acquired. The organ of voice in birds is at the bronchial end of the windpipe, and whatever of articulation they give forth is generated there, though the wind-pipe and mouth may act as a sort of trumpet in increasing the volume of sound, or otherwise changing the pitch of it.

Birds of this genus acquire a very considerable degree of interest, when we come to reflect on the part of their character now stated; and also when we take their usefulness into the account. Some of them at some seasons commit depredations upon the property of man, and destroy numbers of the eggs and young of birds, and also of the young of some mammalia, upon which man sets a value; but these are nothing to the good which they do in return; and it is doubtful whether, without the labours of birds of this genus, any country could be profitably cultivated, not only in so far as concerns plants which are reared for the sake of their seeds or grains, but also as concerns the meadows which are to be grazed. In some districts of Britain it has been felt by experience that the extermination of rooks is any thing but a prudent measure; and, although in many districts a price is set upon the head of the raven, it is questionable whether there be much more wisdom in that. The raven is, in a state of nature, one of the most retiring of the genus, because his habits are different from those of many of the rest; and, therefore, as is the case with the more powerful and predatory creatures of all classes, the raven retires naturally from those places where he is not immediately wanted. In the rich agricultural districts, and the wholesome and abundant sheep-walks, where all the stock is in good condition and free from disease, the raven levies no contribution, except upon such members of wild nature as do not fully participate in the benefit of man's cultivation, and, indeed, he seldom makes his appearance at all. It is generally said, in places where ravens are abundant, and where their manners should be best known, that among domestic animals, even in their young and helpless state, the raven scents nothing but disease. Now, it is well-known that in countries which are poor, badly cultivated, and subject to great variations of winter weather and winter feeding for domestic animals, those animals are not only liable to become diseased in the spring months, but many of their diseases very speedily infect the rest, till mortality becomes very general. These diseases, when they come to the infectious stage, are generally diseases of the alimentary canal, and before they come to this stage, the muscular strength is generally so far subdued that if they are out of doors at pasture, the diseased ones are not able to accompany the healthy, or even to rise up when they have lain down. It is in this stage that both sheep and cattle in exposed situations become ravens' food; and, indeed, in which they attract the notice of these birds; and when they attack calves or lambs, it will generally be found to be those that have been dropped by weakly mothers which are incapable of rearing them.

Thus, it will be found upon examination, that in most cases where there is a raven's portion, and a raven to take it, there is more advantage to what remains in its being so taken, than if it were left. We might easily go over the whole list of these *Corvidæ*, of which the habits are known with any degree of certainty, and show in a similar manner that, in a natural point of view, and even in reference to man's artificial modes of culture, they all do good, and not evil; but the limits within which we must confine this part of the subject, forbid us from saying any more, however interesting it might be to follow up the details. We shall, therefore, only farther mention the leading characters of a few of the principal species, taking those first which are best known in our own country, and commencing with the more powerful ones.

*Corvus corax* (the raven) is the largest and most powerful of all the species, measuring fully two feet in length, at least four feet in the stretch of the wings, and having the tail very firmly feathered, and equal in length to half the body. The plumage over the whole body is black, but glossed with blue reflections, which in certain lights give a very peculiar colour, which is known by the name of raven-grey; and in the extreme north the tint is apt to become paler than it is in warmer climates, and sometimes occasions the description of the bird as two species, whereas all over the world it appears to be the same, without any thing that can be regarded even as a variety.

Raven.

The raven lives in the wilds rather than in the woods, though it nestles in the latter, and builds at a very considerable elevation; and even on the ground, when it does not find other places which are better suited to its habits. When it has a proper choice, however, it prefers the ledges and clefts of rocks, not so high up, or in general in so exposed situations as those in which the eagle builds her eyrie, but rather on the margin of the cultivated grounds, or at all events in places where the vicinity affords plenty of food for it and its brood, which are very clamorous for their meals, and very voracious in the devouring of them. The gape of a young raven is very ample. The nest is formed externally of sticks, and lined with various matters, such as wool or hair. The eggs vary in number, rarely exceeding five, and being very often not more than two. They are of a sort of oil-green colour, with some markings of brownish ash. Ravens

are very attentive to their young and the old ones, which are understood to pair for life, that is, while both live—for no birds remain in widowhood, but pair again (if they can) when the season comes round—are very much attached to each other; they are never far apart, and if danger overtakes the one the other generally makes its appearance, and is not slow at giving assistance. The wariness of the raven makes it very rarely a prey to the stoop of the eagle, or the stroke of the more powerful falcons; and, at close quarters, these are not more than a match for the raven, if, indeed, they are as much. In some cases which have come within the knowledge of the writer of this article, a trained falcon (a peregrine, not a jer) has struck at and clutched a raven, but the raven so returned the clutch that, if assistance had not been given, the falcon would never have struck another bird; for, between the two, it appeared to be very equally “claw for claw,” as the saying is, and it is doubtful whether, if human aid had not come to the falcon, the two would not have been found dead together.

In former times ravens were by no means rare birds, in many, indeed in most parts of the British islands, and in various parts of the country, there was an allegorical saying, “every rock has its raven,” but they are now comparatively rare in England and in the south of Scotland, though there are some in even the eastern parts of the highlands, and more in the west highlands and the isles, where, in consequence of the greater abundance of humidity, and the consequent superiority of growth and abundance of life, they are by no means rare. From the first ridges of secondary hills at the south side of the base of the Grampians, there is, indeed, no want of ravens in most of the waste places, except in the more bleak and uninteresting moors, where there are no spots within many miles properly adapted for being their nesting places. In that part of the country they seldom if ever build in trees, because the principal woods there consist of pines, in which there is not much game suitable for the raven. But in the high and rugged rocks, especially when they have a southerly exposure, and copses and rich patches of land at the base, they are never wanting. In ravens' weather, that is, when the sky lowers and portends storms, or after the storm has just passed, they may be seen upon the more open parts of the woods, sitting on a dark mass of stone and eyeing the desolation around them with keen and cautious glance; and they sometimes vault up to a considerable height, and scan the wide and wild landscape from the top of the sky. They are not the most abundant of the crow tribe which we meet with in these lonely places, and they are not so social or so lively in their manners as most of the others; neither do they, in all probability, commit so many depredations on the nests and young of those birds which breed in the heaths and upland morasses as some of the others. But when you pass near those rocky places which are their favourite haunts and hiding places, it so happens that though you do not always see the raven, the raven always sees you; and he will steal along, by the side of your route, in the trackless desert for many miles, though when you get a sight of him, he appears always to be leaving you, and hopping away to a place in which he himself may be safe. This is done most readily and habitually when there is no sun, and the whole scene wears the dusky hue of the raven. And, though he appears to be always on the retreat, if you sit down you will soon find him

perched on some stone, with his tail towards you, but with the head turned back, and attending with the utmost watchfulness as to whether you are or are not in motion. If you make any demonstration against him, he will get on the wing with much apparent pain and difficulty, and seem as if he were marching off; but he has a curious way of "sideling" on the wing, by means of which he moves in the lateral direction, and gains on you at the end of his flight, even although he has seemed to be retreating all the time. If you wish to watch his manoeuvres in the most perfect manner, or to tempt him within the distance of a shot, the best way is to lie down at full length on your back, and remain motionless. In such a case, if he is at a long distance when you take up your position, he will gain considerably on the wing, by more bold and decided flight than if you are merely sitting. But under no circumstances will he use the wing for the full extent of his reconnoissance; he will alight at a considerable distance, and even if you are so motionless that he feels confident of making a prey of you, he will still approach you in perfect conformity with the tactics of a siege, never upon the direct line, but at an angle, working by traverses more and more oblique as he comes nearer, so that when you observe him in motion, he is always as if he were passing by and regarding you with a mixture of fear and wonder. When he turns at the end of his traverse he stands for a short time as if he were irresolute, and at a loss which way to go, and seems studiously to avoid any appearance of design in his movements. But if you remain quite motionless, he will come very near; and should you allow yourself to doze during his crafty approach, the chance would be that your awaking might cost you an eye; and thus it is better for you to "have an eye" upon him. If you are provided with fire arms, and are inclined to add the useless carcass of a raven to the museum on the barn wall or the stable-yard at the inn, you may, if you have patience enough, make sure game of him; but if you fire and miss him, or if you start up when he is very near you, he mounts the sky, soon clears your horizon, and though you wait ever so long you see him no more.

The raven, when taken young, and the young, in consequence of their clamour, are easily discovered and procured if the nest is accessible (and when it is not, they often fall headlong and are found yelping in their discordant tone among the bushes), is easily tamed, and may be turned to account both as a scavenger and a watchman about tan-yards and other places where there is offal calculated to attract strangers. When these approach, the raven "gives tongue," or rather throat, and if they venture upon his ground, he appears to hop away with one of his legs crippled; but, watching his opportunity, he contrives to jerk himself, like a dart, at the enemy, and as his bill is both strong and sharp, a blow of it will send off a large cur howling. \* These tame ravens take fancies to, and against, persons, and other animals, for which it is by no means easy to account. Without any apparent difference of treatment received by themselves, they will welcome one party, appear to play with them, and never offer any violence; while there are others that they will strike and bite with great bitterness, even when they are fondled.

Ravens, though so voracious, that their name has been generally applied to all who are greedy of food or of any thing else, and not over nice as to the means by which they procure it, are capable of bear-

ing hunger for a very long time. They are so hardy that even in the wildest places, and those where they are most abundant, a dead raven, unless one which has been killed by man, is a very rare sight. They are also understood to be very long-lived, but the number of years is not ascertained. They must, however, be subject to some casualty, as the increase in numbers, in proportion to that of the eggs, is very small. There are ravens in most quarters of the world, if the state of the country is suitable to them, and there is little climatal difference, further than that those which are found in the high polar latitudes are pale in the colour.

We may farther mention as distinguishing features of this species, that the tail is very much rounded; that the feathers on the throat are narrow, sharp pointed, and raised; that those on the back part of the neck are soft and silky; that the bill and feet are black, and that the irides of the eyes consist of two circles of colour, the outer brownish, and the inner pale smoke grey.

*Corvus corone*, the carrion crow, or common black crow. This species is much smaller than the raven, being only about twenty inches in length, twenty-six in the extent of the wings, and eighteen ounces in weight; and as birds, to be equally well winged, should have the wings in the proportion of the cube-roots of their weights, it is not, in proportion, a bird of so powerful flight as the raven. The plumage of this species is entirely black, with few or no metallic reflections, or with them, of a dull green colour; the feathers on the throat being small and narrow, and the webs, toward their points, loose and flocculent; and the tail not so much rounded as that of the raven. Still, the bird has more the air of the raven than that of any other of the family, so that it may, except in colour, pass for a miniature of that bird, with the exception of the gloss of blue on the upper part of the true raven.

The carrion crow, as its name imports, is a foul and miscellaneous feeder. No garbage comes amiss to it, however rank; and it is by no means shy in the search of the offal of all sorts. For these reasons it is sometimes called the "dung-hill" crow, and, in Scotland, the "midden" crow; and it is *the* crow, throughout England. It is very generally distributed; but as the individuals are not in the habit either of flocking on their pastures, or of assembling in numbers to the same herding places, they do not make the same appearance as some of the other members of the genus.

Carrion-crows nestle in trees, generally in more retired places, and farther apart from each other than rooks. They generally pass the summer in extensive forests, from which they occasionally emerge to procure subsistence for themselves and their infant brood. They feed on flesh, eggs, worms, insects, and various kinds of grains; but they are particularly fond of carrion. In spring, they greedily devour the eggs of partridges and quails, and are so dexterous as to pierce them and carry them on the point of their bill to their young; even fish and fruit are not unsuitable to their palate. They often attack the eyes of dying animals, destroy weakly lambs, and, when pressed with hunger, will even pursue birds on the wing. They are notorious for the havoc which they occasion among game and poultry, and in rabbit warrens, where they kill and devour the young. When hens lay their eggs in hedge bottoms, or farm-yards, crows are often caught in the act of devouring them; but when they happen

to be satiated, they will frequently hide their food till hunger becomes more urgent. They have been observed to ascend with a crab to a considerable height and let it fall on a rock to break the shell, and then instantly pounce down upon it and bear it away for immediate consumption. In like manner, a friend of the late Dr. Darwin saw, on the northern coast of Ireland, above a hundred crows preying at once on mussels which they despatched by a similar process. Near the Cape of Good Hope they have been seen to dispose in the same way of land tortoises. We read too of an ill-starred philosopher, in ancient times, who was killed by an oyster impinging on his bald pate, which a crow had mistaken for a block of stone.

During the winter, these birds consort with the rooks and hooded crows, and sometimes intermingle with the latter, so as to give rise to a hybrid race. In this season, numerous flights of various species of the first genus assemble about our dwellings, keeping much on the ground, sauntering much about the flocks and shepherds, hovering near the tracks of the labourers, and sometimes hopping on the backs of pigs and sheep, with such apparent familiarity, that they might be mistaken for domestic birds. At night, they retire into the forests to lodge among the large trees, resorting to the general rendezvous from every quarter, sometimes from the distance of nine miles all around, whence they again sally out in the morning in quest of subsistence. As long as this association lasts, the hooded and carrion crows are observed to grow very fat, while the rooks continue always lean. Towards the close of winter, the latter also remove into other regions, whereas the carrion crows resort to the nearest large forests, where they pair, and seem to divide their territory into districts of about three quarters of a mile in diameter, each of which is allotted to the maintenance of its appropriate family, an arrangement which is said to subsist inviolate during the lives of the separate parties. The female lays from four to six eggs, of a bluish green, and marked with large and black spots, of cinereous grey and olivaceous, and weighing about five drachms each. She sits about three weeks, during which time the male supplies her with food.

The carrion crow often wages war with the lesser species of hawks; but it is especially courageous in the breeding season; nor will it suffer the kite, buzzard, or raven, to approach its nest with impunity. The young do not finally break off connexion with the parents till the commencement of a new brood. As they naturally attack small game, when wounded or exhausted, they have, in some countries, been bred for falconry, as in Turkey, where gentry of inferior quality paint them of different colours, carry them on their right hand, and call them back by the frequent repetition of the syllable *hoob*. Although their flight is neither easy nor rapid, they generally mount to a very great height, and indulge much in a whirling motion. Their croaking in the morning is said to indicate fine weather. As they are exceedingly cunning, have an acute scent, and commonly fly in large flocks, it is difficult to get near them, and still more so to decoy them into snares. Some of them, however, are caught by imitating the screech of the owl, and placing limed twigs on the high branches of a tree; or they are drawn within gun shot by means of an eagle-owl, or such other nocturnal bird, raised on perches, in an open spot. They are destroyed too, by throwing to them garden beans in

which rusty needles are concealed. They are likewise caught by cones of paper, baited with raw flesh. As the crow introduces his head to devour the bait, which is near the bottom, the paper, being besmeared with bird lime, sticks to the feathers of the neck, and he remains hooded; unable to rid his eyes of the bandage, he rises almost perpendicularly in the air, the better to avoid striking against any thing, until, quite exhausted, he sinks down, always near the spot from which he mounted. These, and other modes of ensnaring crows, are chiefly practised in the winter season, when the ground is covered with snow or bound up in frost, for then they more readily approach human habitations, and seek to pick up some subsistence from the dung of animals that have passed along the highways. But many of them are killed, at all seasons, in various parts of the continent, by strewing over the grounds which they frequent, pellets of minced meat, mixed with the powder of nux vomica.

The carrion crow appears to combine the dispositions of two or three other species of the genus. In form, in colours, and in its predatory habits, it resembles the raven; in restlessness and disposition to board, it has considerable analogy to the jack-daw; and in the last of these particulars, as well as in its general cunning, it has some traits of the magpie. It follows the general habit of the whole race in being easily tamed, and taught to repeat words without much difficulty. But still, it has peculiar characters, and belongs to a certain description, or a certain state of countries. It is not a bird of the perfect wilderness, an inhabitant of the open moor or the cliff; neither is it most favourable to those places which are in a high state of improvement. Wooded tracts, which are rather warm and fertile, but somewhat in a state of nature, are the localities in which it is most abundant; and if we are to assign it a topographical position, we may say, that its locality is intermediate between that of the raven and that of the rook. The raven, the carrion crow, the hooded crow, and the rook, may be considered as the typical crows, at least in Europe, and their localities are, the hooded crow, the raven, the carrion crow, and the rook, gradually approaching nearer the cultivated grounds.

*Corvus cornix*, the hooded crow, or, in some parts of the country, the "hoody." This species is considerably larger than the black crow; being about twenty inches long, forty in the stretch of the wings, and upwards of twenty ounces in weight, so that, with the exception of the raven, it is the largest of the crow tribe found in the British islands. Its localities are more peculiar than those of many of the others, but it is very generally distributed over the globe, and in some places of almost all latitudes it is the crow. In England, with the exception of some of the moors in the north, it is a winter visitant, not making its appearance before October, and departing in the spring. But in the north it is much more common, and continues all the year round. In the Lowlands of Scotland it is rather rare, though not quite unknown in any district; but in the Highlands, beyond the line of regular cultivation, it is almost the only crow that is known, with the exception of the raven. It is a strong bird and a powerful fier, and ranges over the moors and mountain bogs, levying very heavy contributions on the nests and young of ground birds, which breed in those places; and when the snow is on the ground, so that it finds but little food inland, it resorts to the shores of the sea and

picks up whatever it can find in that all-productive locality.

It is easily known by its colour, which is smoke grey, with the exception of the head, throat, wings, and tail, which are black, with reflections of a green colour, but more inclining to blue than those of the black crow. It is the contrast of the black on the head with the grey on the back which procures for this species the name of the hooded crow. The hood is not so conspicuous in the female as in the male, because the black is not so deep nor the grey so pale; but the common opinion that the female is without the grey is not correct. The bill is black, but rather paler at the tip, strong and arched in the culmen, bearing a considerable resemblance to that of the raven. The feet are also black, the skin of the tarsi being plated. In the grey parts the shafts of the feathers are black, and the grey is subject to considerable varieties of shade, depending, in part at least, on the latitude and the season; and albinos, or at all events, specimens in which only the shafts of the principal feathers are black, are occasionally to be met with.

Though this species appears in England only in the winter, it is not to be considered as a regular climatal migrant retiring from the northern latitudes during the winter; for it winters as far to the north as the Faroe Islands, and the isles on the coast of Norway, where the shores remain clear of ice during the winter. Those which resort to England and other champaign countries of Europe, where they do not remain during the summer to breed, must therefore be considered as driven from the wilds of Lapland by the want of food. The resort of ground building birds to these wilds during the summer is very great, and hooded crows find an ample supply of provisions in the eggs and callow young; but when the snow falls, or there is not scope and food for them all on the sea-coast, numbers seek their way to more southerly climates.

But it must not, on the other hand, be considered that these birds have any partiality for northern latitudes, other than that they find food plentiful there in the summer season; for they are very generally distributed in all places where there is food for them; and they are the common, or at all events the most frequently seen species of crow in many parts of India, especially in the wild districts near the Runn of Cutch; and we may remark that, generally speaking, where hooded crows remain in large numbers to breed, in whatever latitude it may be, carrion crows and rooks are rarely to be met with. The absence of timber, in such collections as to admit of rookeries, and of such closeness as to hide the nest of the carrion crow, may be partly the reason of this; but still it is doubtful whether it will account for the whole difference. The hooded crow is, for instance, the only crow known in the Shetland and Orkney Islands, and in those wild districts both of the highlands of Scotland and of Ireland, where there are no timber trees; but there are also well wooded districts in the highlands, in which, though hooded crows are abundant, not a single rook or carrion crow is to be seen, though in the lowland districts, distant only a few miles, rooks are abundant, and hooded crows appear only as stragglers. A person passing for the first time from the land of rooks to that of hooded crows, which is nearly synonymous with passing from the country of lowland Scotch to the country of Gaelic,

is apt to imagine that the crows speak a new language as well as the people; for the sound of the rook, if not musical, is at least loud and clear, while that of the hooded crow is at once hoarse and feeble, as if it were a jackdaw attempting to mock the croak of a raven.

Where opportunities offer, the hooded crow breeds in the pines and other large trees, in default of which it nestles in the cavities of rocks. The female, which is rather smaller than the male, and of less lively hues, usually lays four, five, or six eggs, of a greenish blue, marked with many spots of blackish brown. It pairs during the whole of the breeding season, and both parents are much attached to their offspring. They are remarked for their double cry, of which one is hollow and well known, and the other shrill and somewhat resembling the crowing of a cock. When other food is wanting, they will eat cranberries and other mountain fruits; in open fertile countries, they live much on grain, worms, and carrion; but they often resort to the sea shores, and prey on the various animal matters thrown up by the tide. Frisch observes that they are expert at picking fish bones, and that when water is discharged from ponds they quickly perceive the fish which are left in them, and lose no time in darting on them. They not only attack the eyes of lambs and diseased sheep, but of horses that have got entangled in bogs. In the Faroe Isles, where they abound, they are particularly mischievous, picking the seed from the fields, digging up the newly-planted potatoes, destroying the barley before it is ripe, and carrying off goslings and ducklings, or the fish which is hung up to dry, to their young.

*Corvus frugilegus* (the Rook). This species, which is to the inhabitants of well cultivated countries the most interesting of the whole genus, is about the same length as the hooded crow; but it is lighter made, and, when full grown, rather longer in the wings. Its bill too is of a character entirely different, being nearly straight, and having much less of the predatory character than that of any of the three species which have been mentioned. Its bill is bluish black, with a portion of the skin at the base bare of feathers in the full-grown birds, and covered with a scaly scurf of a whitish colour; but in the young birds this portion is covered with feathers, which are projected a little way over the base of the bill. The whole of the plumage is black, but glossed with reflections of purple, violet, and blue, which are very rich and beautiful when the bird is in good condition. The legs and claws are also generally of a black colour. Sometimes, however, but not very often, these birds are subject to variations, not only in the plumage, but in the bill, the claws, and the naked skin. Some are pure white, others piebald, others yellowish, and in these cases the bill, feet, and claws, are generally of a flesh red, but there is always a trace of darker colour in the principal feathers of the wings and the feathers of the tail. Specimens which have these varieties of colour cannot be considered as permanent varieties, and they do not perpetuate their colours in their progeny, neither is it known whether they breed, though it is presumed that they do not. These variations are very rare, compared with the numbers of the birds; and their cause is altogether unknown. The rook is a native of most of the temperate regions of Europe, but is not found much farther north than the south of Sweden, where it breeds, but from which

it is driven by the severity of the winter. In Russia and the west of Siberia, it is far from rare, emigrating early in March to the environs of Woronetz, and mingling with the common crows. In England they are stationary, but in France, Silesia, and many other countries, most of them are birds of passage. In France they are the forerunners of winter, whereas in Siberia they announce the summer. Their flights are sometimes so dense as to darken the air, being frequently joined, not only by the common crow and jackdaw, but also by troops of starlings. Every spring they resort to breed on the same trees, preferring the loftier branches, and building sometimes ten or twelve nests, which are one above another on the same tree, whilst a great many trees thus furnished occur in the same forest, or rather in the same district. They seek not retirement and solitude, but rather settle near our dwellings. When a pair are employed in constructing the nest, one remains to guard it, while the other is procuring the suitable materials; for otherwise the structure would, it is alleged, be instantly pillaged by the other rooks which have fixed on the same tree, each carrying off a twig to its own dwelling. Rookeries are sometimes scenes of violent contests between the old and the new inhabitants, whether the intruders be of the same or of different species. A pair which had in vain attempted to establish themselves in a rookery at no great distance from the Exchange of Newcastle-upon-Tyne, having been compelled to abandon their purpose, took refuge on the spire of that building; and though constantly interrupted by others of their own species, succeeded in completing their nest at the top of the vane, and reared their young, apparently regardless of the noise of the people underneath. The nest and its inhabitants were in course turned round by every change of wind, and yet the parents persevered in maintaining the same position for ten years, when the spire was taken down. As soon as rooks have finished their nest, and before they lay, the male begins to feed the females, which receive their bounty with a fondling tremulous voice, fluttering wings, and all the little blandishments that are expected by the young while in a helpless state. This gallant deportment of the males is continued through the whole season of incubation. The female lays four or five eggs, which are smaller than those of the raven, but marked with broader spots, especially at the large end. After the young have taken wing there is a general deserting of the nest trees, but the families return again to them in October to roost, and to repair their dwellings. On the approach of winter, however, they usually seek some more sheltered situation at night, but generally assemble first in the usual place, and then fly off together. Their autumnal exercises of departing on their foraging excursions in the morning, and returning in the evening, are familiar to ordinary observation, and have been well described by White and others. Though the forest may be said to be their winter habitation, they generally visit their nurseries every day, preserving the idea of a family, for which they begin to make provision early in spring, the business of nidification being usually accomplished in the month of March.

The rook has but two or three notes, and makes no great figure in a *solo*; but when he performs in *concert*, which is his chief delight, these notes, though rough in themselves, being intermixed with those of the multitude, have, as it were, their ragged edges

worn off, and become harmonious, especially when softened in the distant air. So marked is their dread of a fowling-piece, that the country people allege they even smell gunpowder; but, if the gun be carefully concealed from their view, a person with his pockets full of gunpowder may approach very near them. Among the favourite articles of their food is the grub of the chafer, or beetle, which, if allowed to multiply unchecked, would lay waste whole meadows and cornfields. It must not be dissembled, however, that rooks themselves are sometimes very injurious to new sown wheat, just when it begins to germinate. The severity of winter, when accompanied by a heavy fall of snow, sometimes drives them down to the sea-shore, where they are observed to feed on small shell-fish, particularly the common periwinkle. Having raised these last into the air, to about the height of fifty feet, they let them fall among stones, stooping instantly after their prey. If the shell is unbroken, they lift it again and again; and when the wind happens to carry it out of the perpendicular direction, they toil much and gain little. Frauds in the mode of procuring their livelihood, as well as in that of building their nests, are sometimes attempted among them, but which, when discovered, meet with instant and condign punishment. Indeed we can scarcely doubt that these sagacious birds have ideas of property, unknown to many of the inferior animals, as each pair, year after year, assert their claim to the same nest; and an attempt to invade them, on the part of others, would, as often happens, be punished not merely by the aggrieved individuals, but by the combined efforts of the society, which clearly proves that they consider it as an offence against the community. When tamed they evince both confidence and attachment.

The young of this species are, by some, reckoned good for the table, but those habituated to better fare will probably esteem them somewhat coarse. In order to be at all edible, they must be skinned, and, even then, they are exceedingly bitter, and not very nourishing; but the abundance in which they may be had where there are extensive rookeries, renders the shooting of them when they are "branched," that is, when they have left the nest but not taken to the wing, rather a favourite exploit with the more humble description of sportsmen. The sport is, however, both cowardly and cruel, not greatly superior to that of shooting pigeons from a trap; and the lamentations which the parent birds make over their slain progeny are not only painful to hear, but have a very strong expression of reproach in them; and the feelings thereby produced are not lessened when we consider the perfect confidence with which rooks congregate near human habitations, and the great services which they render to the cultivator.

*Corvus monedula*, (the Jackdaw), or steeple crow, called in Scotland the *kae*, which is very nearly the sound of its natural voice. It is about fourteen inches in length, twice as much in the stretch of the wings, and weighs about nine ounces. The head is black, the nape of the neck is smoke grey, the back greyish black; the wing-coverts and secondary quills black, with violet reflections; the under part bluish black; the bill and legs also black, and the irides whitish grey. This species is noisy, and, when tamed, it is mischievous; but in its general habits it resembles the rook, in rarely plundering the nests of other birds; but rather feeding upon insects, worms, and various sorts of seeds.

The jackdaw, though it affects peculiar localities,

and chiefly towers in cliffs, is not absolutely confined to such places, even in its nest-building. It is also very generally distributed over Europe, stationary in some countries, but migrant in others, without any uniform regard to difference of latitude. On the extreme north of Europe it is indeed only a summer visitant, there being no food for it in the winter. In Sweden it is found pretty far to the north. It winters about Upsal, and passes the night in large flocks in ruined towers, especially those of the old town. It is common all over Russia and Western Siberia. In the south of Russia, and in Great Britain, it is stationary throughout the year; but in France, some parts of Germany, and other places, it is at least partially migratory, though a number of them continue in these countries during summer. Such of them as migrate form themselves into large bodies, like the rooks and hooded crows, whose phalanxes they sometimes join, continually chattering as they fly. Yet they observe not the same periods in France and in Germany, for they leave the latter in autumn, and appear not again till the spring, after having wintered in France. In general they frequent old towers, ruined buildings, and high cliffs, but they also occasionally breed in the holes, and even on the branches of trees, especially if in the neighbourhood of a rookery. In some parts of Hampshire, owing, probably, to the want of towers and steeples, they frequently build in the burrows of a rabbit-warren; and in the Isle of Ely, from a similar cause, they take up their abode in chimneys. Their nest is made of sticks, and lined with wool and other soft materials, and the eggs are generally five or six, smaller and paler than those of the crows, of a bluish or greenish ground, spotted with black or brown. After the young are hatched, the female watches, feeds, and rears them with an affection which the male seems eager to share. Some authors affirm that they have two broods in the year, but this, we have reason to believe, is by no means uniformly the case. During the season of courtship they prattle incessantly, woo each other's society, and even kiss. Even in captivity they refrain not from these marks of tender attachment. Many pairs usually nestle in the same neighbourhood. They feed principally upon worms and the larvæ of insects, and are very fond of cherries. Their voice is shriller than that of the rook or crow, and appears to be capable of different inflexions. They are easily tamed, and seem so fond of domestication as seldom to attempt their escape. They may be fed on insects, fruit, grain, and even small pieces of meat. With no great difficulty they may be taught to articulate several words; but they are mischievous and tricky, and will secrete not only portions of their food, but pieces of money and jewels.

*Corvus pica*, or *Pica melanoleuca* (the Magpie). This is a species with lively colours, the peculiar attitudes, the prying disposition, and the familiar manners of which every body is acquainted with. Its length is about eighteen inches, but great part is taken up by the tail, and the body is rather short and round; the extent of the wings is about two feet, and they are broad and rounded, and better adapted for ascending and descending than for long flights, upon which the bird flies with rapid movements of the wings, and apparently with difficulty. The weight is about nine ounces; the bill and legs are black; and the irides deep and bright brown, which gives very

considerable expression to the eye. This is altogether one of the most beautiful of British birds, and if it were not so common it would be very much admired. Its colours are black, with purple and green reflections; the scapulars, breast, belly, and inside of the wing-feathers, white; tail lengthened and wedge-shaped; the black, especially on the feathers of the wings and tail, exhibits, in certain dispositions of the light, very fine reflections of green, blue, purple, and violet, a circumstance of which superficial observers are little aware; nor can he who has only examined a dirty specimen, in confinement, form any adequate notion of the native beauties of the bird. It is about eighteen inches long, twenty-four in extent of wing, and weighs between eight and nine ounces. The female differs from the other sex only in being somewhat less, and having a shorter tail. Among the more remarkable varieties to which it is occasionally liable, we may notice that of whiteness almost pure, cream or buff colour, and white streaked with black.

The magpie is generally diffused in England, France, Germany, Sweden, and most of the countries of Europe; and it also occurs in Asia as far as Japan, in China, as well as in Siberia, Kamschatka, and the adjacent islands, whence it has possibly passed into the northern parts of America, for it is seen, though rarely, in Hudson's Bay, and on the borders of the Mississippi. In Europe it is found as far north as Wardlines, and as far south as Italy; but it seldom abounds in hilly regions. Being smaller than the rook, and with wings proportionally shorter, its flight is neither so lofty nor so well supported; neither does it undertake long journeys, but only flies from tree to tree, at moderate distances; yet it is seldom at rest for any length of time, but skips and hops about, and shakes its long tail almost incessantly. Though naturally shy and distrustful, yet it is seldom found remote from human habitations. Magpies generally continue in pairs throughout the year; and if they sometimes unite into small flocks, it is only for some temporary purpose. They are clamorous and mischievous, reject hardly any species of animal food or fruits, and devour grain when nothing else is within their reach. They will prey on birds caught in snares, on nestlings, rats, field-mice, young poultry, leverets, feathered game, carrion, fish, and insects. Lambs, and even weakly sheep, they attempt to destroy, by first plucking out their eyes. They are notorious pilferers and hoarders, and will conceal either provisions, or any glittering objects, with great address, pushing them into holes until they are no longer visible. Their winter store of food is usually collected in the middle of a field, and is sometimes indicated by two of the species contending for the hoard. Though crafty, they are also familiar; and though naturally addicted to chatter, they are still more so when tamed and attached; so that, especially when taken young, they may be taught to pronounce words, and even short sentences, and will imitate any singular noise. In their natural state they proclaim aloud any apparent danger, inasmuch that no fox, or wild animal, can appear without being noticed and haunted; and thus even the fowler is frequently deprived of his sport, for all birds seem to know the magpie's alarming chatter. The nest, which is placed on the top of a tree, in a thick bush or hedge, and sometimes at no great distance from the ground, bespeaks much skill and artifice. The male and female work at it

conjointly, or alternately, beginning in February, and usually continuing their labours for six weeks or two months. It is, for the most part, constructed on a fork, or on a junction of branches, and composed of twigs, young shoots of trees, and a thick covering of leaves, strengthened outwardly with long and flexible sticks, plastered over with mud, the upper part being covered with thorny branches, closely matted, so as to secure a retreat from other birds intruding, a hole being left at the side scarcely large enough for the admission and egress of the parent birds. The inside is furnished with a sort of mattress, composed of the fibres of roots, wool, and other soft materials, being only six inches in diameter, whereas the whole edifice measures at least two feet in every direction. Should the eggs be destroyed, the female abandons a construction which had cost her and her partner so much trouble, and will lay a second, and even sometimes a third time, if again disturbed, the number of eggs diminishing at each hatch. On these occasions she does not build a new nest, but takes possession of, and refits, an unoccupied one that has belonged to a rook, or else finishes one of those imperfect structures which are occasionally to be found in her neighbourhood, as if purposely reserved for cases of emergency. But, if unmolested, there is but one brood, which generally consists of seven or eight. The eggs are of a bluish or pale green, spotted with brown, and cinereous. The male and female incubate alternately, and in the course of about fourteen days the young are brought forth blind, and continue so for some days. The parents rear them with great solicitude, and for a considerable length of time. During winter nights, magpies assemble in great numbers in some coppice or thicket to roost, but they separate again in the day-time. When the young are taken from the nest for training, they may be fed with bread, curdled milk, or new cheese. Their flesh is considerably inferior to that of the young rook. In almost every country, the appearance of the magpie is, in the minds of the vulgar, associated with superstitious and ominous notions.

The prying, pilfering, and nest-plundering propensities of the magpie, sometimes subject it to a little temporary inconvenience at the hands of boys, especially where it has young in a thick tree near the house. An egg is emptied of its contents by blowing, and then filled with bird-lime, and laid in some place where it may be seen by the magpie; and as "Madge" has all her eyes about her, and knows most of what is within the range of her observation, the exposure of the egg out of doors is as easy a matter as the concealing of it. She soon approaches, watchful of any one who may be observing her, but intent upon the egg. After a hop or two in various directions, to see that all is safe, she dashes her bill into the egg, in the usual way of carrying the larger kinds of eggs to her brood; but as the shell is already broken, the bill penetrates up to the eyes, and the shell adheres, and acts as a blind. She takes flight, however; but, as she cannot see her way, she flies bumping against the twigs, and often cuts a very ridiculous figure before she can so disentangle herself from the shell and the bird-lime as to be able to see her way.

When magpies are holding those councils, or "folk-motes," for which they are so remarkable, a scene of great consternation ensues among them if one of the more powerful hawks come in sight, or if

a falcon is flown over them. All chattering and hopping is instantly at an end, unless there are bushes into which they can creep; and when they are within reach of no such shelter, they remain motionless on the ground; though, in places where large hawks frequently appear, they select their rendezvous in some spot which is closely surrounded by broom or furze, or some other cover. As long as the hawk or falcon remains in sight, the whole powers of the magpies seem to be absorbed in the dread of it; for they may be knocked down with a stick with little attempt to escape, or taken with the hand without offering any resistance. But we must close our notice, for there is really no end of the stories that might be told of this very curious bird.

*Corvus glandarius* (the Jay). In some respects the jay stands nearly in the same relation to the magpie that the carrion crow does to the rook. It is a woodland bird, never found in open and treeless places, and very seldom near houses. In the woods it chooses the thickest shades; and though its chatter is often heard, it is less frequently seen than almost any other bird of the same size and equally numerous. It occurs in all parts of the British islands where there is cover for it, and it has an original name both in Welsh and Gaelic, both of which have the same meaning, "wood-screacher," or "wood-screamer;" and some systematists have made it the type of a separate genus, under the name *Garrulus*.

The jay varies a good deal in size with the nature of its haunts, being much smaller in Scotland than in England. Its mean dimensions may be taken at about a foot in length, eighteen or nineteen inches in the stretch of the wings, and about seven or eight ounces in weight.

The bill of the jay is dusky, the legs brown, and the irides of a glistening pearl grey, which gives a sharp and irritable expression to the eye. The head is whitish, with black streaks, and the feathers on the top of the head are loose, and form a crest which is erectile at pleasure. The body is wine buff, or a mixture of yellow, red, and brown, so melted into each other, that the whole effect is not easily described. The lesser coverts of the wings are pale bay; the greater coverts are marked with traces of black and rich blue. The secondary quills next the body are bay, with black tips, the next two are entirely black, and the remaining ones are black, tinged with blue, and having white on their outer necks, near the base. The rump and tail coverts, both upper and under, are white, and the tail feathers black. These birds, though they keep in the cover of the woods, are very active and very voracious. They are omnivorous, consuming great quantities of nuts, mast, wild cherries, peas, and other products of the wood and its vicinity; they are also great robbers of the nests of smaller birds, and they sometimes kill and eat the birds themselves, and also mice, and the larger insects. They are in fact always prying about in the warm season, and very often eating. It is usually said that they are in the habit of hoarding their vegetable food against the season of want; and it may be true, for there are a good many more birds which form magazines than we are usually in the habit of giving credit for being so provident. But, in the case of the jay, this is not easily established by actual observation, as it is by no means easy to see what they do; and though they are found making free with a store, it cannot, on

account of their habits, be thence inferred that this store is their own. In confinement they do conceal their surplus provisions, but they at the same time pilfer and hide substances which can be of no use to them as food; so that no certain conclusion can thence be drawn of what they may do in a state of nature; and magpies and jackdaws both hoard and steal when in a domesticated state, and yet we do not hear of their stores of provisions being met with when they are in the wild state. In winter, too, at least in the colder parts of the country, jays are understood to be, for the greater part of their time, in holes of trees, or other places of concealment, in a state nearly dormant. It is not supposed that they actually hibernate, but they are rarely seen at that season when there are no leaves on the trees to conceal them; and when they do make their appearance in winter, it is only on very mild days.

When any danger appears, the jays set up a screaming, and as their chattering is loud, and they all take up the note, they alarm the whole tenants of the wood, and thus, by acting the part of sentinels, make some sort of return to other birds for the depredations which they commit on their nests. On some parts of the continent they are partially migrant, and where this is the case they partially flock, though their flocks can hardly be called societies. In Britain they are more stationary, generally remaining in the same places, and rearing two broods in the course of the season. They choose the most close and concealed parts of the trees for their nests; and, both for general habitation and nesting, they prefer young woods, in which the trees are branched down nearly to the ground, to those which have tall and clean boles. Rooks and jays may be found in the same forest, but not in the same part of it. The nest is not so elaborate a structure as that of the magpie. It is broad, and rather firm, as well as carefully concealed; but it has no dome, and is shallow, and without any very soft matters in the lining. The eggs vary from four to seven, are smaller than those of the pigeon, of a greenish-grey colour, with olive spots. The time of the incubation is understood to last about two weeks.

When the jay has grown to maturity in the wild state, it is very shy as well as cunning, and can hardly be reconciled to confinement by any means; but when it is taken young, it is very easily tamed, and very docile, though even then it appears at times to be very impatient of the confinement of the cage, against which it breaks its feathers, and often does itself more serious injury. But it articulates readily, can be taught a number of tricks, and therefore, in many parts of the world it is kept with much attention. Its voice is flexible, and it is capable not only of articulating words, but of imitating the voices both of other birds and of several of the mammalia. For food it is of little value, as it is both tough and of bad flavour; but on some parts of the continent it is eaten, after having undergone the double culinary process of being first boiled and then roasted. Even if it were good, the labour of obtaining it in Britain would be far more than its value; but on the continent it is more easily obtained; and though it is not in request for the table under its own name, it is said to be sometimes double-cooked, as above-mentioned, and then introduced as a thrush.

*Corvus graculus* (Chough). This species, which is called the Cornish crow, the red-legged crow, and

various other names, is an inhabitant of peculiar localities, but these localities are situated in many latitudes, and they are sometimes on the sea-coast, and sometimes inland. In all places, however, it appears to be a rock-bird, though not an inhabitant of all rocks indiscriminately, or even of all rocks which appear to be in themselves of nearly the same character.

In Britain the chough is found only on, or very near, the coast, and on those coasts only which are washed by the Atlantic and the Channel, and not upon these, if there are not rocks or lofty ruins to serve it for nesting-places. Dover and Cornwall, some parts of Wales, and a few spots on the west coast of Scotland and the Hebrides, are the British localities of the chough. It occurs as far to the north as Norway, and in the rocky mountains of central and southern Europe, in the Alps, the Pyrenees, &c. It is also found, at least at some seasons of the year, in places where there are few or no rocks, being particularly abundant along the banks of the Nile in Egypt, when the inundations begin to subside, and the supply of reptile food becomes abundant; but it does not breed on the banks of that river.

The chough is black, with a tinge of violet; and the bill and legs are red. The irides are hazel. The bill is differently shaped from that of any of the previously mentioned species of the genus, being longer in proportion, more slender, and bent for nearly the whole length, though only slightly. It is also much weaker, being brittle, and therefore not adapted for the hard labour to which the bills of some of the others are subjected. Of course it is used for different purposes, and the form and texture of the bill, together with the character of the haunts in which it is chiefly found, may help to guide us to the particular nature of its food, and consequently to the part which it performs in the economy of nature. The character of the feet is also of some importance; they are very stout, or at least clean made for the size of the bird, and the claws are crooked and sharp, partaking a little of the prehensile character.

Chough.

Thus the bill of the chough is not adapted for digging into the ground, or for pushing and breaking hard substances, like the bills of most others of the genus, nor are its feet adapted for scraping; it must therefore be a surface feeder, and its food animal or soft vegetable matter, or both. There are many small animals on the bank of the river which has been inundated, for the mud in such places, if the

climate or even the weather for the time is hot, becomes absolutely alive; and there are many similar creatures on the ocean strand, where the ebbing and flowing of the tide occasions something like an inundation, and its departure twice every day. Besides the animal food which it finds in those places, the chough is said to be very fond of those wild berries which are generally abundant in the humid or marshy parts of the uplands, and these furnish it with at least a seasonal supply. Scopoli mentions that choughs feed much upon juniper berries, which, as they take a long time in growing, and are in several successions upon the bushes at the same time, continue ripening for a longer period, and are ripe more in the dry season than the annual crops; and they are followed by the *vacciniums* and other berries of swifter growth and shorter harvest. In this the chough follows the same practice as the crows in the mountainous parts of our own country, which may be seen in the mountain marshes and other places which abound with berries after the nesting is all over, and there is little for them to plunder in the more dry and heathy parts of the moors.

Choughs take a good deal of care in the construction of their nests. These are usually formed in the crannies of the rock, about midway up the cliff, so as to be out of the reach of danger both from below and from above. There are a good many materials used, sticks to form the frame-work, and then a copious lining of wool, hair, or other soft matters, as may happen to be within the reach of the birds. The eggs are usually about four or five in number, rather larger than those of the jackdaw, of a dull white colour, with spots of ash colour and pale brown, which are most abundant at the larger end.

Choughs seldom come abroad in stormy weather, but they are much on the wing when it is fine, flying high to and from their feeding grounds, and often uttering their cries, which are more shrill and wailing than those of jackdaws. They are very easily tamed, and get familiar and even attached to those with whose appearance they are familiar; but they are not fond of strangers. The difference of their notes to those they know and those they do not are worthy of attention to their acquaintances. Their tones of address are soft and even coaxing; but they utter a very harsh alarm note when any one whom they do not know approaches them. As is the case with all the race, they are very apt to steal and secrete pieces of money and other shining substances; and in cottages, where sticks are burnt, they are apt sometimes to seize little pieces which are on fire at one end, and fly about with them in a way not altogether safe.

*Corvus caryocatactes* (the Spotted Crow or Nutcracker.) This species is not uncommon on the continent of Europe; and it generally appears there in flocks; but in Britain it occurs only in straggling specimens, and that very rarely. It is a very handsome bird, about the size of a magpie, or about thirteen inches long, and a foot and a half in the stretch of the wings. The general colour of the body is dusky brown, all marked over with triangular white spots. The crown of the head, the wings, and the tail, are blackish, the latter marked with white at the tip, and the middle feathers with the ends of their webs ragged and incomplete.

There are some points of resemblance between the nutcracker and both the magpie and the jay; but the bill is of a different shape, the mandibles being

straighter, blunter at the point, and of unequal length. Its attachment to localities is also different. It comes not near houses, like the magpie, neither does it dwell in thick woods and copses on the rich grounds. It is more of a mountaineer, seeking the forests upon the elevated slopes, nestling in holes, and finding the chief part of its food in the kernels of trees, nuts, acorns, beech mast, the seeds of the conifers, and other vegetable substances, which, in consequence of the hardness of their envelopes, remain on the ground as a store for nearly the whole season. The hardest of these it can readily break, and it is for this reason that it is called the nutcracker. From the retired nature of its habits in keeping to the wild woods at that season when the knowledge of it would be most interesting, very little is known of the domestic economy of the nutcracker; and all that is known in Britain, save the mere appearance and colour of the bird, judged of from a casual straggler or a museum specimen, is at second hand. It is alleged by Klein, and some other of the continental describers, that there are two varieties, or even species, in the Alpine forests of central Europe—one with the bill strong and angular, and the tongue long, and forked; and another with the bill rounder and weaker, and the tongue also divided at the tip, but much shorter than that of the former. It is further said that the one with the angular bill and the long tongue fairly breaks the shells of the nuts, while the other merely pierces them and extracts the kernel through the opening. Their nests are in the holes of trees; and when they do not meet with these to suit their purposes, they are said to make them, or at all events to work them to the desired shape; but, as we have already noticed, their habits are imperfectly known. The eggs are said to be about five or six in number, of a greyish fawn colour, and marked with spots of clear brown.

The nutcracker is not understood to have so much cunning, or to be so much of a thief, as the magpie or the jay, though it is described as still retaining the omnivorous character, and sometimes varying its food by making a meal of another bird, the skull of which it very quickly hammers to pieces with its powerful bill. Adult birds of this species are said not to be tameable, as they obstinately refuse to take food; but young ones can be tamed with nearly the same facility as others of the genus. In confinement they are said to be given to hoard and pilfer like the rest of the tribe, but whether they have this habit when in a state of nature is not known.

On the continent this species is very generally distributed, being found not only on the wooded mountains of Europe, but in Siberia, as far as Kamtschatka. Seasonally they leave the woods, and appear in considerable flocks, and in the flocking season they are often seen both in Germany and France.

There are very many foreign species, either belonging to this genus or very nearly allied to it, in almost every part of the world; but we have not room for even a mere catalogue of the whole; and their manners, in so far as they differ from those of the species already noticed, are so little known that they could not easily be made interesting to the general reader. We shall therefore close this very imperfect sketch by a mere notice of one or two of the most remarkable species.

*Corvus cristatus*—*Garrulus cristatus* of Cuvier (the Blue Jay of America). This is a very beautiful species, resembling, in many of its habits, the common

jay of Europe. It is very generally distributed over at least the more temperate parts of North America; and we cannot bring it so well before the reader as in the language of that prince of all ornithologists, Alexander Wilson.

"This elegant bird," says this eloquent child and worshipper of wild nature, "which, as far as I can learn, is peculiar to North America, is distinguished as a sort of beau among the feathered tenants of our woods by the brilliancy of his dress; and like most other coxcombs, makes himself still more conspicuous by his loquacity and the oddness of his tones and gestures. The jay measures eleven inches in length; the head is ornamented with a crest of light blue or purple feathers, which he can elevate or depress at pleasure; a narrow line of black runs along the frontlet, rising on each side higher than the eye, but not passing over it; back and upper part of the neck a fine light purple, in which the blue predominates; a collar of black, proceeding from the hind head, passes with a graceful curve down each side of the neck to the upper part of the breast, where it forms a crescent; chin, cheeks, throat, and belly, white, the three former slightly tinged with blue; greater wing-coverts, a rich blue; exterior sides of the primaries, light blue, those of the secondaries a deep purple, except the three feathers next the body, which are of a splendid light blue; all these, except the primaries, are beautifully barred with crescents of black, and tipped with white; the interior sides of the wing-feathers are dusky black; tail long and cuneiform, composed of twelve feathers of a glossy light blue, marked at half inches with transverse curves of black, each feather being tipped with white, except the two middle ones, which deepen into a dark purple at the extremities. Breast and sides under the wings a dirty white, faintly stained with purple; inside of the mouth, the tongue, bill, legs, and claws, black; iris of the eye hazel.

"The blue jay is an almost universal inhabitant of the woods, frequenting the thickest settlements as well as the deepest recesses of the forest, where his squalling voice often alarms the deer, to the disappointment and mortification of the hunter; one of whom informed me, he made it a point, in summer, to kill every jay he could meet with. In the charming season of spring, when every thicket pours forth harmony, the part performed by the jay always catches the ear. He appears to be among his fellow musicians what the trumpeter is in a band, some of his notes having no distant resemblance to the tones of that instrument. These he has the faculty of changing through a great variety of modulations, according to the particular humour he happens to be in. When disposed for ridicule, there is scarce a bird whose peculiarities of song he cannot tune his notes to. When engaged in the blandishments of love, they resemble the soft chatterings of a duck, and while he nestles among the thick branches of the cedar, are scarce heard at a few paces distance; but he no sooner discovers your approach than he sets up a sudden and vehement outcry, flying off, and screaming with all his might, as if he called the whole feathered tribes of the neighbourhood to witness some outrageous usage he had received. When he hops undisturbed among the high branches of the oak and hickory, they become soft and musical; and his call of the female a stranger would readily mistake for the repeated squeakings of an ungreased wheel-

barrow. All these he accompanies with various nods, jerks, and other gesticulations, for which the whole tribe of jays are so remarkable, that with some other peculiarities they might have very well justified the great Swedish naturalist in forming them into a separate genus by themselves.

"The blue jay builds a large nest, frequently in the cedar, sometimes on an apple tree, lines it with dry fibrous roots, and lays five eggs of a dull olive, spotted with brown. The male is particularly careful of not being heard near the place, making his visits as silently and secretly as possible. His favourite food is chestnuts, acorns, and Indian corn. He occasionally feeds on bugs, caterpillars, and sometimes pays a plundering visit to the orchard, cherry rows and potato patch; and has been known in times of scarcity to venture into the barn, through openings between the weather boards. In these cases he is extremely active and silent, and, if surprised in the fact, make his escape with precipitation, but without noise, as if conscious of his criminality.

"Of all birds he is the most bitter enemy to the owl. No sooner has he discovered the retreat of one of these, than he summons the whole feathered fraternity to his assistance, who surround the glimmering *solitaire* and attack him from all sides, raising such a shout as may be heard in a still day more than half a mile off. When in my hunting excursions, I have passed near this scene of tumult, I have imagined to myself that I heard the insulting party venting their respective charges with all the virulence of a Billingsgate mob; the owl meanwhile returning every compliment with a broad goggling stare. The war becomes louder and louder, and the owl at length, forced to betake himself to flight, is followed by his whole train of persecutors, until driven beyond the boundaries of their jurisdiction.

"But the blue jay himself is not guiltless of similar depredations with the owl, and becomes in his turn the very tyrant he detested, when he sneaks through the woods, as he frequently does, and among the thickets and hedge rows, plundering every nest he can find of its eggs, tearing up the callow young by piecemeal, and spreading alarm and sorrow around him. The cries of the distressed parents soon bring together a number of interested spectators (for birds in such circumstances seem truly to sympathise with each other), and he is sometimes attacked with such spirit as to be under the necessity of making a speedy retreat."

*Corvus Canadensis* (the Canada jay) is by no means so showy a bird as the former. It is described as being "eleven inches long, and fifteen in the extent of the wings; back, wings, and tail, a dull leaden grey, the latter long, cuneiform, and tipped with dirty white; interior vanes of the wings brown, and also partly tipped with white; plumage of the head low and prominent; the forehead and feathers covering the nostrils, as well as the whole lower parts, a dirty brownish white, which also passes round the bottom of the neck like a collar; part of the crown, and hind head black; bill and legs, also black; eye dark hazel. The whole plumage on the back is long, loose, unwebbed, and in great abundance, as if to protect it from the rigours of the regions it inhabits.

"A gentleman of observation, who resided for many years near the North River, not far from Hudson, in the state of New York, informs me that he has particularly observed this bird to arrive there at the

commencement of cold weather; he has often remarked its solitary habits; it seemed to seek the most unfrequented shaded retreats, keeping almost constantly on the ground, yet would sometimes, towards the evening, mount to the top of a tree, and repeat its notes (which a little resemble those of the baltimore,) for a quarter of a hour together; and this it generally did immediately before snow or falling weather."

*Corvus ossifragus* (the fishing crow). This is another North American species, which is worthy of notice on account of the peculiarity of its habits. They are wholly aquatic birds; and are scavengers upon the numerous and productive waters of that part of the world, especially of those which are near the coast. They are birds of powerful wing for their size, and furnished with large and crooked claws. They hover along over the surface of the waters, and are ever and anon twitching down to seize in their claws any dead fish or other garbage that may be floating. They are most abundant in the southern part of the States, where the waters are more productive; they are understood to perch and nestle in high trees near the waters; and they are very common about fishing villages and fishing stations. It does not appear that they depend much on the land for their food, or in any way injure its cultivated produce. The following is the description:—they are sixteen inches in length, and thirty-three in the stretch of the wings; black all over, with reflections of steel blue and purple; the chin is bare of feathers around the base of the lower mandible. Upper mandible notched near the tip, the edges of each turned inwards about the middle; eye very small, placed near the corner of the mouth, and of a dark hazel colour; recumbent hair or bristles, large and long; ear feathers, prominent; first primary little more than half the length, fourth the longest; wings when shut reach within two inches of the tip of the tail; tail rounded and seven inches long from its insertion; thighs, very long; legs, stout; claws sharp, long and hooked, hind one the largest, all jet black. Male and female much alike.

Besides those which we have noticed there are many species or varieties in different parts of the world; but the manners of them all are very similar; and it is exceedingly probable the climatal varieties of those which are common with us, have been described as different species.

**CORYPHÆNA** Coryphene; the dolphin of the ancients. A genus of spinous-finned fishes, with abdominal fins, situated immediately under the pectorals, and thus referable to the thoracic fishes of the Linnean system; but included in the mackerel family (*Scomberoidæ*) in Cuvier's structural arrangement. They are numerous, and vary much in size, in colour, and in several other of their external appearances; but their generic characters are well made out, and there is a good deal of similarity in the habits of them all. The leading characters are:—The body compressed, elongated, and covered with very small scales, the head short, and truncated on the upper part; the gill-lids smooth, and with seven rays in the gill-flap; the dorsal fin beginning immediately behind the head, and ranging the whole length of the back, its rays of nearly the same flexibility throughout the whole length, but those of the anterior part have no articulation. All the members of this genus are pelagic fishes, enjoying free range of the wide sea, in the deep water rather than over the banks, remaining and

feeding near the surface. They are generally splendid in their appearance; and in point of colour, at least, they are among the most beautiful inhabitants of the deep. The brilliancy of their colours vanishes in death; so that it is impossible to form any idea of them from museum specimens, how carefully soever these may be prepared and preserved.

This holds, indeed, with regard to all the more splendid fishes; and, as the tints and lustres which they display, have a transparency about them, which does not belong to even the finest colours of land animals, so they have an evanescence, which renders it impossible to form any idea of them, unless when they are seen alive and in health. Those of this species, in particular, pass through a number of beautiful rainbow tints, while they are in the agonies of death; and this was one of the reasons why the luxurious Romans were so very fond of having coryphenes at their sumptuous entertainments; they did not, however, serve up these fishes, at least in the first instance, in the style in which fishes are served up at the tables of modern epicures. They brought them to table alive, so that the company might enjoy the luxury of seeing them die. After this they were withdrawn, cooked, and brought back again as an article of food.

Coryphenes are most abundant in the tropical seas, though some of them are found in the Mediterranean, but there are none in the polar seas, or, indeed, in very high latitudes, though it is probable that they extend farther into the southern hemisphere than the northern. They are remarkable for energy of life; and the radiant and finely varying tints which they display are living lustres, and add greatly to the beauty of the wide seas.

When they are coursing over the sea in shoals, which they generally do, though the shoal is never of wearisome extent, and the bright sun of the tropical sky is beating on them through a thin and continually varying stratum of water, and when they themselves are shooting along with the rapidity of flashes of lightning, they form an exhibition, than which there are few more beautiful in nature. Indeed, gorgeous as are many of the flowers in tropical countries, and gay as are many of the birds, their colours do not refract, and decompose, and reflect the light and return it in such an endless variety of tints, all liquid, as if they were molten in the element in which the creatures live, as is done by the fishes.

The sublimity of the wide sea, and the steady trade wind soon falls upon the sense; and, as there is little to be done on board ship in such places, and the heat is relaxing to Europeans, a passage there would be a very dreary matter, were it not for the sporting of the fishes, and of the long-winged birds, which rival the coryphenes in seeking their prey over the extensive ocean.

In such situations a shoal of coryphenes presents a rich treat to the spectator; nor is it by any means a passing glory, like a meteor in the sky, to be viewed only for a moment, and talked of afterwards as a thing of memory. They keep company with the ship for days, and even for weeks, ranging along for hundreds of miles; and, though the rate of sailing is considerable, it is in fine weather nothing at all to the speed of swimming in the coryphenes. They play round and round the ship, now shooting a-head, now getting astern, on the starboard at one time, and on the larboard at another. In every position of themselves and the light they are brilliant; but in no two posi-

tions of either one or the other are they exactly the same. At one time they are gold, at a second emerald, at a third sapphire, at a fourth amethyst; then they are carbuncle and ruby, and so on through every imaginable colour, named or unnamed; and in all they have that radiance which we have mentioned as, among living creatures, belonging only to the inhabitants of the deep. Nor are these uniform changes of the whole shoal; for as they do not all maintain the same posture, the same attitude, or the same depth in the water, the whole of this variety is given to the eye at once, so that it seems as if every varied beam into which the utmost radiance of a tropical sun can be divided were in continual play over them.

Then there is another part of the accompaniment which, though it has not all the innocence of this beautiful display of varied colours, is not without interest in its own way. These fishes cannot perform their rapid motions, so much exposed to the action of the sun, without considerable waste of their system; for it is a law of nature, that powerful action, of whatever kind it may be, requires support and renewal of substance in proportion to its energy. Hence the coryphenes are exceedingly voracious, and it is their voracity which makes them follow the ship with such persevering assiduity. Not, of course, that they expect to eat the ship; though they are not very particular as to the quality of what they swallow; but there is always some sort of fat thrown overboard, and this forms the chief attraction which ships have for those fishes that follow them.

It is singular how such an opinion of the acuteness of smell in fishes could have originated, as the parties have evidence of its falsehood constantly before their eyes. Every one knows that there is nothing peculiarly tempting to the olfactory nerves of a trout, in an artificial fly or an artificial minnow, and yet, when skillfully managed, these are as successful as real baits. The very fishes in question too, and indeed the whole mackerel family, seem to hesitate so short a time about smells, that a bit of scarlet rag, tin plate, bright shell or brass button, is taken by them just as readily as any other bait. Even in some of the soft-finned fishes which seem to have the olfactory nerves a little more developed, there appears to be an equal incapacity of distinguishing between what is food and what is not. When the workmen were occupied in erecting the light-house on the Bell-rock, they found the water over some parts of that rock so thick of whittings that they literally concealed the bottom for an extent of many yards; and they were as voracious as they were numerous, and as heedless as either; for the men had only to tie a crooked brass pin to the end of a bit of string, and so draw up whittings in any quantity they chose. But to return to the coryphenes.

All that these fishes can glean from the refuse thrown overboard from a ship would, of course, not support the millionth part of their number; and consequently they must be provided with other food, otherwise they could not exist in nature. One staple article with them is the flying fishes (see *EXOCETUS*), which they pursue with nearly the same assiduity as the porpoise pursues salmon, but with much greater success and more splendid effect; and, if any comparison could be instituted between land predatory animals and sea ones, one might say that the porpoise more resembles a bear on the pursuit, and the coryphene more a leopard; for the porpoise is ugly in its colour, and lumbering in its motions, while the coryphene is swift

and beautiful. In both cases the prey, when the case becomes one of extremity, attempts to escape by leaping out of the water; and, though the salmon falls instantly, and, generally speaking, into the mouth of its pursuer, while the flying-fish can keep in the air a little, as if it were supported on wings, yet its flight is short, and it not only increases the chance of being captured by the coryphene, but also subjects itself to as great danger from another enemy, the albatross or some other pelagic bird. Thus, it appears, that the flying-fish has rather an under share of piscine enjoyment. It is usually said that fishes, exempted from the burden of themselves in the air, and also from the vicissitudes of that element, have really nothing to do but enjoy one continual feast by eating one another; for which feast their amazing fertility affords a plentiful supply, in which all that man takes for his use is not missed.

It is not supposed that the flesh of any species of coryphene is poisonous; but, from the fleetness of their motions it is hard, dry, and tasteless, yet that of many of the species is eaten.

Cuvier divides the genus into several sub-genera, which we shall barely notice:—

*CORYPHENES*, properly so called. These have the body compressed, the head very much raised, the profile arched, the outline descending very rapidly to the muzzle, the eyes situated very low down, teeth on the palate as well as the jaws, and they are of larger size than the others. Their dorsal fin, which is very handsome, extends all the way from the nape to the tail; the caudal fin is forked in some, straight in others, and in others again rounded or pointed.

*Coryphæna hippuris*—common coryphene. This is the largest species of the whole, attaining the length of at least five feet. It occurs in the Mediterranean, and also in the oceans near the tropics. Its dorsal fin is long, with its edge nearly parallel to the line of the body, and the fork in the tail is deep. The back is bright sea-green, mottled with small orange spots; the belly is silvery; the lateral line yellow, the dorsal fin bright sky-blue, with gold coloured rays; the caudal fin greenish; and all the remaining fins yellow. This species is the dolphin of the ancient fables.

Three or more species have been enumerated by systematic writers, as belonging to the forked-tail subdivision of true coryphenes; but it is exceedingly difficult to determine what is a species, and what is not, in fishes which are so active and so highly coloured; and, as the difference between the one and the other does not appear to relate much either to structure or to manners, it is comparatively of little importance. The statement usually made is, that those species which occur to the south-eastward of Asia are brighter in colours, smaller in size, and even more rapid in their motions, than those which occur in the Mediterranean and the Atlantic; but their motions are so flat, and they are so seldom seen, that we cannot come to any positive conclusions respecting them. We may, however, just mention one or two of the most beautiful of this species.

*Coryphæna aurata* (the golden coryphene). This species is found in the Indian seas, is very rare, and has not been met with of so large a size as the coryphene of the Mediterranean. Its dorsal fin is shorter, and all blue without the gold-coloured rays. The tail is deeply forked, and all over of the colour of polished gold. The body consists of an endless variety of brilliant colours, which it is not possible to describe.

*Coryphæna Boryi*. This species is described as inhabiting the intertropical part of the Atlantic, and as differing in its shape from both the former, it being enlarged at the middle, so as to approach the form of the flat fishes. It has not been found more than two feet in length; and it is reported as affording more savoury food than the others.

It is described as being the most beautiful of all the fishes. The dorsal fin is high at the fore part, and gradually diminishes to the tail. It is of the most brilliant ultra-marine blue, marked with bright lines of rich indigo blue. The upper part of the head is a rich brown, passing through very fine tints of emerald green on the back into golden yellow on the sides and tail. The margin of the yellow is delicately marked with greyish; and the belly is silvery. All the fins, except the caudal and the dorsal are yellow. The caudal is deeply divided, or rather it consists of two separate fins attached to the extremity of the animal.

*Coryphæna chrysurus*—golden-tailed coryphene. This species is found in the south sea. Its body is very elongated. Its tail is of a remarkably brilliant gold colour, the back azure, the dorsal fin blue, spotted with yellow, the under part silvery, and all along the upper part marked with lenticular spots of deep blue, very numerous, and placed irregularly.

*Coryphæna lutea*—yellow coryphene. This species is described as being an inhabitant of the Indian seas, chiefly yellow on the upper part, and silvery on the under. Both this and the species immediately preceding, are described as being most assiduous in capturing the different species of flying fishes. The species with the tails straight or rounded, or lancet-shaped, have chiefly been observed in the eastern seas; and it is probable that they ought not to be included in this sub-genus, and some of them not in this genus at all.

**CENTROLOPUS.** This division of the genus have two spinous prominences in front of the dorsal fin, but the spines are so short that they can be felt only by pressing the finger pretty strongly against the skin. Their bodies are compressed, their scales small, their head longer than that of the true coryphenes, but obtuse at the muzzle. One species of this division has acquired some celebrity, at least it possessed some in ancient times on account of its attendance upon vessels. This is,

*Coryphæna pompilus*, so called as it forms part of the cortege or train of the ship. It is about a foot in length, diminishing in thickness towards the tail, feels greasy to the touch; its back is marked with yellow bands, and there are golden yellow stripes above the eyes resembling eyebrows. This species is found both in the Mediterranean and the Atlantic.

**LEPTOPODES.** This division, like the former, has dorsal prominences barely discoverable by the finger; but it differs in having the dorsal and anal fins running into each other, so as to form a pointed tail.—There is only one known species (*Leptopodes Ater*), which is a little fish, feeble, and timid. It is found in the Mediterranean, in the deep water, during the greater part of the year, but approaches the shore about the month of August for the purpose of spawning. It is about six inches in length; the general colour is deep black, with violet reflections. Its muzzle is rounded, its eyes small, with golden irides. In the spawning season it might be taken in any quantity, but its flesh is soft and insipid, and good for nothing.

There are many important particulars to be learned from the careful study of those pelagic fishes which range far and wide over the sea; and no species of them are calculated to afford us more information in this respect than the mackerel family; because they live more exposed than almost any other fishes, and, therefore, they serve better as indexes to the general economy of nature in the sea. But in proportion as their manners and the influence of varying seasons upon them are important, they are difficult to be studied; because the sea is a wide surface, of which man can see but a small part at once, and we do not meet with the same inhabitants, or even the same water, when we twice visit the same spot.

**COSSUS.** A genus of lepidopterous insects, belonging to the family *HEPIATIDÆ*, which see.

**COTINGA**—Ampelis. A genus of American birds, belonging to the fly-catching tribe of the dentirostral division of Cuvier's great order *Passeres*, and ranged between the fly-catchers properly so called and the bee-eaters. These birds were ranged by the elder ornithologists, along with many others, in a very extensive genus, but they have been since subdivided. The cotingas, properly so called, all inhabit the rich and humid forests of America. They are conspicuous for the rich colours of their plumage, in which purple and blue are the prevailing tints.

The characters are: the bill of mean length, a little depressed, higher than wide, three cornered at its base, flattened at its point, moderately hard; upper mandible convex, with a ridge on the culmen, and notched towards the point; which is curved; the inferior mandible a little flattened on the under side; nostrils at the sides of the base, round, half closed with membrane and by some silky feathers; feet of mean size, three toes to the front, one behind; the two outside, in front, united to the second; and the hind toe the same length as the outer one; wings rather short, the first quill shorter than the second, which is the longest in the wing.

As restricted by Cuvier, the genus *Cotinga* is a very peculiar one, and does not contain a very great number of species. The birds which compose it are all of a wild and retiring character, shy and silent, having nothing in their conduct or their sounds at all corresponding to the brightness of their covering. They are found only at those parts of America which have a strictly tropical climate, and even in these, they are confined to moist and shady situations which abound with insects, though they are also understood to live, in part, upon soft and sugary fruits. They are not, however, so destructive to plantations as many other birds that have the same mode of feeding; but though they are retiring, and also confined within geographical limits, they are not absolutely stationary; yet, the only object of their little voyage is, to arrive in certain places at the epoch in which the fruits they subsist on are mature. In Guiana, the spots in which they most delight, in those seasons when they are seen near habitations, are humid places. It is an error to suppose that they are destructive to the rice grounds. From the peculiar conformation and absence of solidity in their bill, it is impossible that they can be granivorous birds. According to Sonnini, the inhabitants do not eat their flesh, and if the stuffed specimens often arrive in Europe in a bad state, this is not the reason; it is rather, because the feathers not being very adherent, the tender skin requires a degree of care in its preparation, which is not always

bestowed upon it in America. The size of the cotinga varies from that of the raven to that of the song thrush. The colours of the females are, in general, much less rich than those of the males; their plumage is, indeed, frequently dull and dusky. The habits of these birds, and the facts concerning their reproduction, are very imperfectly known; many species, however, are known to make their nests on the loftiest trees, and lay four or five eggs.

As the same parts of the forests in which these birds nestle, are inhabited by climbing quadrupeds, which are much disposed to plunder both eggs and young, the birds take the precaution of building at heights, and under circumstances of concealment, which make their broods pretty safe, not only from quadruped enemies, but from nest-plundering birds, of which there are many species in the luxurious forests of tropical America. Thus, the cotingas, in their quiet way, contrive to get on as well in their domestic economy as the most noisy tenants of the forest. Their general history is a short one: they live in the very richest places of the world, feed well, wear handsome clothing, dwell in secure habitations, and take as little fatigue as they possibly can. We shall just mention one or two of the species.

*Blue Cotinga*.—Plumage bright azure, with the exception of the head, neck, and breast, which are rich purple; the quills and coverts, and also the bill and feet, are black. These are the colours of the male bird, and the length is about eight inches and a half. The female is of a blackish brown with purple reflections on the under part, and each feather slightly bordered with white. Head and under tail-covert red. The young, while in their nest, in plumage resemble the female. This species is found in Guiana.

*Brazil Cotinga or Blue Riband*.—This is a very beautiful species, rather smaller than the former. Its upper part is exceedingly bright azure blue; the under part rich violet purple, with a band of black crossing the breast, the quills, and the coverts. The bill and feet are black. The young have the under part marked with small flame-coloured spots.

There are three or four species more, which appear to be tolerably well defined and established, and there are some others which are doubtful; but, as we have already said, there is not much of interest in the manners of the birds, nor would there be more to the general reader in merely running over changes or markings of colour, however beautiful.

**COTTON**, is the name of the plant, as well as of the flaccuous substance produced by the *Gossypium*, *Herbaceum*, *Vitifolium*, &c., of botanists. Linnæan class and order, *Monadelphia Polyandria*, and natural order, *Malvaceæ*. Generic character: involucre large, three-cleft, persisting, segments heart-shaped; calyx goblet-shaped, five-toothed; petals inversely heart-shaped; stamens united in a cylinder; anthers kidney-shaped; style columnar; stigmas three or five; seed-vessel three-celled and three-valved; seeds enveloped in wool. It is almost unnecessary to observe, that this is one of the most useful plants known, and not only to the warmer parts of Asia, where it is cultivated, but to every other part of the civilised world, whether favourable to its culture or not. As an article of commerce and manufacture, it rivals the fleeces of the northern latitudes, and perhaps employs as much, or more capital, than any other branch of trade whatever. For further particulars, see **MALVACEÆ**.

**COTTUS** (Bull-head). A genus of spinous-finned fishes, belonging to Cuvier's division of *Joues cuirassées*, or fishes with hard plates on the cheeks, and which he ranks immediately after the perch family. The relations of the family will be pointed out shortly in the article **HARD CHEEKS**, and more at length in the general article **FISH**, so that we shall only, in this article, have to notice the generic characters, adding some short notice of the species, particularly of such as are British.

The most general description which can be given of this genus of fish is,—that they are all very small and very ugly, and, at the same time, of little or no use to man; but, from their very general distribution, they must answer some important purpose in the economy of nature, and there is little doubt that they are also of much indirect importance to the human race, in affording food to larger and more valuable fishes.

The generic characters are: the head large and depressed, furnished with hard plates on the cheeks, which are variously armed with spines and tubercles; two dorsal fins; teeth in the advanced part of the vomer, but none in the palatal bones; six rays in the gills, and three or four only in the ventral fins. They have no air bladder.

The head is disproportionately large, flattened, and has the eyes turned upward, which gives them an unhandsome appearance; their colours also are very dull, and their skin is, in general, covered with a mucous secretion, so that they slide through the fingers of those who offer to catch them. They are found both in the fresh waters and in the sea, but the greater number are inhabitants of the fresh waters, and these have the head always smooth and only one spine on the gill-lid. They are, though small, lively and active fishes, lurking under stones and in small holes of the banks and bottoms, from which they issue with great rapidity, and seize fry-worms, the larvæ of aquatic insects; but as some of them inhabit fresh water and others salt, and as the ones that have these different haunts have also necessarily different manners, it will be desirable to treat each species by itself. Of the enumerated species, at least five are natives of Britain; and as, though they are not of much value in an economical point of view, they are of some curiosity as subjects of natural history, we shall give some notice of each of them.

*Cottus gobio*, the river bull-head, miller's thumb, tommy logge, and various other names. This species seldom exceeds four inches or four and a half in length; its head, though flattened, is broad, but its body is very slender. It is pretty generally distributed over Europe, being found in most of the small streams of fresh water from Italy to Russia; but it is found only in gravelly places, or, at least, where the water is not impregnated with peat, and, for this reason, it is not general in Scotland or in Ireland, except in the north-east part of the country, where there are no peat bogs. Its flattened head and hard cheeks enable it to poke itself under stones; and thus, as its motions are very quick, it is not seen without some difficulty. Those who are curious in tracing the origin of popular names, suppose it is called the bull-head in consequence of the size of its head, though it probably receives this appellation as much from its wrinkled front. "The miller's thumb" has given rise to various other speculations. Some have said that the thumb of a miller derives a particular shape, resembling that of the head of this fish,

from his thumbing the meal to try if it is properly ground. But it is probable that the mere fact of the fish being found pretty generally in mill-streams may have given origin to the name; for the head of the fish is more like the thumb of a cobbler than that of a miller. As this species is greasy to the feel and insipid to the taste, and as it contains little flesh, good or bad, it is not eaten in this country; but it is said to be eaten in Italy; and that, in some parts of the north of Europe, it is hung up, exactly balanced, in order that by the direction of its head it may tell how the wind sets, which, of course, it does not do unless exposed to the wind.

The particular characters of this species are: the mouth wide, the jaws of nearly equal length, with numerous pointed teeth in both jaws, and also on the anterior part of the vomer; the head spinous; pupils of the eyes dark blue, irides yellow; gills ending in a flattened point; a membrane between the two dorsal fins; rays of all the fins spotted; upper part blackish brown; sides lighter, spotted with black, under part white. This species deposits its spawn in summer.

*Cottus bubalis* (father-lasher, long spined-cottus). This is a very formidable looking fish, and from its shape, its numerous spines, and a variety of other peculiarities in its appearance, it is a fish of some interest. It belongs to the cold seas rather than to the warm; and though it is rarely met with on the British shores of more than from six to nine inches in length, it grows much larger in the extreme north, and the natives of Greenland are said to make a sort of soup of it, similar to that which is made of the haddock in Scotland. In ordinary cases the father-lasher expires the moment it is taken out of salt water and put into fresh, but by gradually passing through the brackish water it is said to be able to ascend the estuaries for the purpose of depositing its spawn, which it does about the month of January. It is by no means uncommon on the British shores, and is frequently left, at low water, in small pools among the rocks, and when it is attempted to be caught by the hand it puts on rather a formidable appearance, by distending its gill-covers, erecting the spines, and making motions as if it were disposed to strike right and left at any one who might attempt to seize it.

We know not what may be the cause, but there are many parts of the east coast of Scotland where this fish is more frequently found dead on the beach than any other species; and as we have generally met with its body upon gravelly beaches where the current runs strong, it may be that it gets entangled among the stones and stranded, or that the want of an air-bladder may prevent it from managing itself well in turbulent water.

Notwithstanding the frequency of the dead body of this fish on the places of the coast that have been alluded to, it is by no means a delicate fish, but on the other hand remarkably tenacious of life. It is well observed by Mr. Yarrell, in his work on British fishes, now in course of publication, that the largeness of the gill-openings of fishes, cannot be the only cause why they die soon when taken out of the water. All fishes which have the gill-lid armed with erectile spines, have more power over it than those which possess no such armature; and we may naturally conclude, that they are able to move these with less derangement to the fibres of the gills when these are not supported in water.

The head of the father-lasher has some resemblance to that of a lurking predatory quadruped, with its ears laid backwards against its neck, and prowling for prey. The eyes are very near to each other, and the sight directed vertically, their colour, black pupils with yellow irides, gives them a little the air of those of a wild beast; and this is further heightened by the elevation and straightness of the frontal ridges. These ridges are continued quite to the nape, where they end in two spines; there are also four spines upon the pre-operculum, of which the upper one is of considerable length; one on the scapula, and a clavicular one on each side, and two on the nose. The colour on the upper part is dark brown, mottled with red brown, the under part is white. There has been some confusion between this and another marine species, although in appearance there is a good deal of difference between them. This other species is—

*Cottus scorpius* (the sea scorpion, or short-spined cottus). This is also an inhabitant of seas far to the north, and understood to grow to a larger size in cold latitudes than in those which are more temperate; and though it is not very likely, still it is possible that it may seek the more southerly haunts for the purpose of spawning. With us it is about the same size as the other, and it is found abundantly in many parts of the shore. In its general appearance it holds a sort of middle place between the river bull-head and the father-lasher. The head is large, more elevated than that of the bull-head, with a prominent ridge between the eyes and the snout, and a spine on each side of it. There are no spines on the nape, but there are three short ones on the pre-operculum, and two on the operculum itself. The colour is nearly the same as that of the former species, but the shape of the fins is different, and the ventral fins are attached, posteriorly, to the belly of the fish by a membrane. It is understood that this species spawns much later in the year than the father-lasher, which latter species spawns in January.

*Cottus quadricornus*. This is also a northern species, being much more frequent on the northern shores of Europe than in the temperate countries, though it is by no means rare on some parts of the east coast of Britain; and it is understood that this is about the last fish that is met with in the extreme north. There are four horned tubercles on the upper part of the head, from which it gets the name of four horned. It has three spines on the pre-operculum, and one only on the operculum. The body of it is more elongated than that of the other species; the head is brown, with some red on the gill-covers, the sides yellowish, and the belly white; the fins are finely clouded and mottled. It grows to be a little larger than any of the others, at least it grows longer; but it is seldom used unless as a bait for other fish.

This species comes much more rarely on the British shores, so as to be taken in the pools at low water, than any of the former; but it is not unfrequently met with by the fishers for sprats.

All the marine species of this genus are understood to be voracious, and to feed chiefly upon the fry of other fish, and upon small crustaceous animals, which last they catch in great numbers among the sea weed. They cannot be considered as giving any very striking character to the places which they inhabit, inasmuch as they are but of diminutive size, do not crowd in numerous shoals, and are of little value. They have, however, a distinct geographical

locality, and therefore, they must, in so far, form an index to the general economy of nature in that locality, if we could but once become acquainted with their manners.

The allied tribes which used to be included in the same genus, but are now separated from it, differ in some of their characters; but it may not be amiss here to mention one of them, which is still popularly, at least, considered as a bull-head. This is,

*Aspudorus Europæus*, the armed bull-head or pogge, the characters of which are: the body eight cornered, covered with scaly plates, and tapering toward the tail. The head thicker than the body, snout with red coloured spines, and teeth in both jaws, but none on the vomer. Two distinct dorsal fins, but smaller than those of the former species. This is a northerly fish also; but in summer it is found in most of the sandy bays, near the mouths of rivers on the east coasts of Britain: it is small, not above six inches in length, but its flesh is described as being firmer and better than that of the true cotta.

**COW-BUNTING, or CATTLE-BIRD** (*Molothrus pecoris*, Swainson). "There is one striking peculiarity in the works of the great Creator," observes Wilson, the historian of the birds of the United States, "which becomes more amazing the more we reflect on it, namely, that he has formed no species of animals so minute, or obscure, that are not invested with certain powers and peculiarities, both of outward conformation and internal faculties; exactly suited to their pursuits, sufficient to distinguish them from all others; and forming for them a character, solely and exclusively their own. This is particularly so among the feathered race. If there be any case where these characteristic features are not evident, it is owing to our want of observation; to our little intercourse with that particular tribe; or to that contempt for inferior animals, and all their habitudes, which is but too general, and which bespeaks a morose, unfeeling, and unreflecting mind. These peculiarities are often surprising, always instructive when understood, and, (as in the subject of the present article,) at least amusing, and worthy of being farther investigated."

"The American cattle-bird, the subject of the present memoir, is a small bird, about the size of the European sky-lark, and belongs to the natural family *Sturnidae*, or starling tribe; forming one of the many connecting links between that family and the *Fringillidae*, or finches. It is closely allied to the troopials (*Aglais*), or the genus to which the common red-winged black-bird (as it is locally called) of North America belongs; but is even more finch-like, or rather bunting-like, in its form, and so very peculiar and remarkable in its habits and history, that it cannot exactly be classed in the same division with any other known species. The form of the bill is very nearly that of the true bunting (*Emberiza*), but straighter, and more starling-like in its outline; and the general shape of the body is about the same as that of the troopials, only rather more finch-like; its length is about seven inches, and extent of the wings eleven inches. The head and neck are of a very deep silky drab, and the upper part of the breast a dark changeable violet; the rest of the bird black, with a considerable gloss of green when exposed to a good light. Tail, slightly forked; legs and claws glossy black, strong and muscular; iris of the eye dark hazel. The female is, all over, of a brown colour, somewhat paler underneath, and the young male birds are, at first, altogether brown, and,

for a month or more, are naked of feathers round the eye and mouth; the breast is also spotted like that of a thrush, with light drab and darker streaks. In about two months after they leave the nest, the black commences at the shoulders of the wings, and gradually increases along each side as the young feathers come out, until the bird appears mottled on the back and breast with deep black and light drab. At three months the colours of the plumage are complete, and, except in moulting, are subject to no periodical change. The sexes also are alike in size, and do not exhibit, in this respect, the remarkable disparity which is observed in all the troopials.

"The most remarkable trait in the character of this species is, the unaccountable practice it has of dropping its eggs into the nests of other birds, instead of building and hatching for itself, and thus entirely abandoning its progeny to the care of strangers. More than two thousand years ago, it was well known, in those countries where the bird inhabits, that the cuckoo of Europe (*Cuculus canorus*)"—See Cuckoo—"never built herself a nest, but dropt her eggs in the nests of other birds; but, among the thousands of different species that spread over that and other parts of the globe, no other instance of the same uniform habit has been found to exist" (save, however, in one or two other species of *Cuculus*), "until discovered in the bird now before us. Of the reality of the former there is no doubt; it is known to every school-boy in Britain; of the truth of the latter I can, myself, speak with confidence, from personal observation, and from the testimony of gentlemen, unknown to each other, and residing in different and distant parts of the United States."

These are the words of Wilson; and, as those of an original observer are always far better than any abstract that can be made of them, we will here copy his description of the habits of this singular species at some length, intending also to give a rather detailed account of those of the European cuckoo; the peculiarities of the one being found to throw not a little light upon those of the other. "The circumstances," he continues, "by which I became first acquainted with this peculiar habit of the bird are as follow:—

"I had, in numerous instances, found, in the nests of three or four particular species of birds, one egg much larger, and differently marked from those beside it; I had remarked, that these odd-looking eggs were all of the same colour, and marked nearly in the same manner, in whatever nest they lay, though frequently the eggs beside them were of a quite different tint; and I had also been told, in a vague way, that the cow-bird laid in other birds' nests. At length I detected the female of this very bird in the nest of the red-eyed fly-catcher, which nest is very small, and very singularly constructed;" (a neat pensile nest, hung by the two upper edges, and very firm and durable). "Suspecting her purpose, I cautiously withdrew without disturbing her, and had the satisfaction to find, on my return, that the egg which she had just dropt, corresponded as nearly as eggs of the same species usually do, in its size, tint, and markings, to those formerly taken notice of. Since that time, I have found the young cow-bunting, in many instances, in the nests of one or other of these small birds. I have seen these last followed by the young cow-bird, calling out clamorously for food, and often engaged in feeding it; and I have now, in a cage before me, a very fine one, which, six months

ago, I took from the nest of the Maryland yellow throat, &c. \* \* \* I claim, however, no merit for a discovery not originally my own, these singular habits having long been known to people of observation resident in the country, whose information, in this case, has preceded that of all our school philosophers and closet naturalists, to whom the matter has, till now, been totally unknown.

"About the twenty-fifth of March, or early in April, the cow-pen bird makes its first appearance in Pennsylvania from the South, sometimes in company with the red-winged blackbird," (or troopial, *Aglaius phœniceus*), "more frequently in detached parties, resting, early in the morning, an hour at a time, on the tops of trees near streams of water, appearing solitary, silent, and fatigued. They continue to be occasionally seen, in small solitary parties, particularly along creeks and banks of rivers, so late as the middle of June; after which we see no more of them until about the beginning or middle of October, when they re-appear in much larger flocks, generally accompanied by numbers of the red-wings" (troopials); "between whom and the present species there is a considerable similarity of manners, dialect, and personal resemblance. In these aerial voyages, like other experienced navigators, they take advantage of the direction of the wind, and always set out with a favourable gale.

\* \* \* \* \*

"From the early period at which these birds pass in the spring, it is highly probable that their migrations extend very far north. Those which pass in the months of March and April, can have no opportunity of depositing their eggs here," (in the United States,) "there being not more than one or two of our small birds which build so early. Those that pass in May and June are frequently observed loitering about solitary thickets, reconnoitering, no doubt, for proper nurses, to whose care they may commit the hatching of their eggs and the care of their helpless orphans. Among the birds selected for this duty are the following. \* \* \* The bluebird" (*Sialia Wilsonii*), "which builds in a hollow tree; the chipping sparrow" (*Emberizoides socialis*), "in a cedar bush; the golden-crowned thrush-pit" (*Sciurus auricapillus*), "on the ground, in the shape of an oven; the red-eyed fly-catcher" (*Vireo olivaceus*), "a neat pensile nest, hung by the two upper edges on a small sapling or drooping branch; the yellow-bird" (or American gold-finch, *Carduelis luteus*), "in the fork of an elder; the Maryland yellow-throat" (*Trichas personatus*, a little bird somewhat allied to the European hedge chanter), "on the ground, at the roots of brier bushes; the white-eyed fly-catcher" (*Vireo noveboracensis*), "a pensile nest, on the bending of a vine; and the small blue-grey fly-catcher" (*Culicivora cærulea*), "also a pensile nest, fastened to the slender twigs of a tree, sometimes at the height of fifty or sixty feet from the ground. There are, no doubt, others to whom the same charge is committed; but all these I have myself met with acting in that capacity.

"Among these, the yellow-throat and the red-eyed fly-catcher appear to be particular favourites, and the kindness and affectionate attention which these two little birds seem to pay to their nurslings, fully justify the partiality of the parents.

"It is well known to those who have paid attention to the manners of birds, that, after their nest is fully

finished, a day or two generally elapses before the female begins to lay. This delay is, in most cases, necessary to give firmness to the yet damp materials, and allow them time to dry. In this state it is sometimes met with, and laid in by the cow-bunting; the result of which, I have invariably found, to be the desertion of the nest by its rightful owner, and the consequent loss of the egg thus dropt in it by the intruder. But when the owner herself has begun to lay, and there are one or two more eggs in the nest before the cow-bunting deposits hers, the attachment of the proprietor is secured, and remains unshaken until incubation is fully performed, and the little stranger is able to provide for itself." There is a little here at variance with the habit of the cuckoo of Europe, which is, always to destroy whatever other eggs there may be in a nest into which she introduces her own; any eggs, therefore, which are ever found together with that of the cuckoo, have usually not been laid till after its deposition; never, in fact, but in cases where the cuckoo had been disturbed, as she sometimes is by the proper owners of the nest, before she had had time to finish her operations; an instance of which was once observed by the writer of this.—See Cuckoo.

"The well known practice of the young cuckoo of Europe," continues Wilson, "in turning out all the eggs" (?) "and young which it feels around it, almost as soon as it is hatched, has been detailed in a very satisfactory and amusing manner by the amiable Dr. Jenner\*, who has since risen to immortal celebrity in a much nobler pursuit, and to whose genius and humanity the whole human race are under everlasting obligations. In our cow-bunting, though no such habit has been observed, yet still there is something mysterious in the disappearance of the nurse's own eggs soon after the foundling is hatched, which happens regularly before all the rest. From twelve to fourteen days is the usual time of incubation of our small birds; but although I cannot exactly fix the precise period requisite for the egg of the cow-bunting, I think I can say almost positively, that it is a day or two less than the *shortest* of the above-mentioned species! In this singular circumstance we see a striking provision of the Deity; for, did this egg require a day or two more, instead of so much less, than those *smaller* eggs among which it has been dropped, the young it contained would, in every instance, most inevitably perish; and thus, in a few years, the whole species must become extinct. On the first appearance of the young cow-bunting, the parent being frequently obliged to leave the nest to provide sustenance for the foundling, the business of incubation is thus necessarily interrupted; the disposition to continue it abates; nature has now given a new direction to the zeal of the parent, and the remaining eggs, within a day or two at most, generally disappear. In some instances, indeed, they have been found on the ground near, or below, the nest; but this is rarely the case.

"I have never known more than one egg of the cow-bunting dropped into the same nest. This egg is somewhat larger than that of the blue-bird" (that is to say, about the size of that of the yellow-bunting of Europe), "thickly sprinkled with grains of pale brown on a dirty white ground—it is of a size propor-

\* See Philosophical Transactions for 1788. Part II.

tionable to that of the bird"—the European cuckoo's is not.

"So extraordinary and unaccountable is this habit, that I have sometimes thought it might not be general among the whole of this species in every situation, that the extreme heat of our summers, though suitable enough for their young, might be too much for the comfortable residence of their parents; that, therefore, in their way to the north, through our climate, they were induced to secure suitable places for their progeny; and that, in the regions where they more generally pass the summer, they might, perhaps, build nests for themselves, and rear their own young, like every other species around them. On the other hand, when I consider that many of them tarry here so late as the middle of June, dropping their eggs, from time to time, into every convenient receptacle; that in the States of Virginia, Maryland, Delaware, New Jersey, and Pennsylvania, they uniformly retain the same habits; and, in short, that in all these places I have never yet seen or heard of their nests,—reasoning from these facts, I think I may safely conclude, that they never build one; and that in those remote northern regions their manners are the same as we find them here.

"What reason nature may have for this extraordinary deviation from the general practice, is, I confess, altogether beyond my comprehension. There is nothing singular to be observed in the anatomical structure of the bird that would seem to prevent or render it incapable of incubation" (nor is there in that of the European cuckoo). "The extreme heat of our climate is probably one reason why, in the months of July and August, they are rarely to be seen here; yet we have many other migratory birds that regularly pass through Pennsylvania to the north, leaving a few residents behind them, which, without exception, build their own nests and rear their own young. This part of the country also abounds with suitable food, such as they usually subsist on. Many conjectures, indeed, might be formed as to the probable cause, but all of them that have occurred to me are unsatisfactory and inconsistent. Future and more numerous observations, made with care, particularly in those countries where they most usually pass the summer, may throw more light on this matter, till then, we can only rest satisfied with the reality of the fact.

"This species winters regularly in the lower parts of North and South Carolina and Georgia; I have also met with them near Williamsburgh, and in several other parts of Virginia. In January, 1809, I observed strings of them for sale in the market of Charlestown, South Carolina. They often frequent corn and rice fields, in company with the red-winged troopials, but are more commonly found accompanying the cattle, feeding on the seeds, worms, &c., which they pick up amongst the fodder and from the excrements of the cattle, which they scratch up for this purpose"; which, be it remarked, is often the habit of the European starling (*Sturnus vulgaris*). "Hence they have pretty generally obtained the name of Cow-pen-birds, Cow-birds, or Cow-blackbirds. By the naturalists of Europe they have hitherto been classed with the finches, though improperly, as they have no family resemblance to that tribe sufficient to justify that arrangement" &c.

"Respecting this extraordinary bird," says Wilson, "I have received communications from various

quarters, all corroborative of the foregoing particulars. Among these is a letter from Dr. Potter of Baltimore, which, as it contains some new and interesting facts, and several amusing incidents, I shall, with pleasure, lay before the reader, apologising to the obliging writer for a few unimportant omissions which have been anticipated in the preceding pages." The limits, however, of this Cyclopædia will not allow us to transcribe the whole of this highly interesting communication; we will select only a few of the more important facts, but we heartily recommend the reader to peruse the original, the details of which evince a habit of patient investigation, and a degree of philosophic caution, which naturalists in general would do well to imitate.

"The cow-pen finch differs, moreover," says the writer, "in another respect, from all the birds with which I am acquainted. After an observance of many years, I could never discover anything like pairing or a mutual attachment between the sexes. Even in the season of love, when other birds are separated into pairs, and occupied in the endearing office of providing a receptacle for their offspring, these birds are seen feeding in odd as well as even numbers, from one to twenty, and discovering no more disposition towards perpetuating their species than birds of any other species at other seasons, excepting a promiscuous concubinage which pervades the whole tribe." The same obtains in the European cuckoo. "When the female separates from the company, her departure is not noticed; no gallant partner accompanies her, nor manifests any solicitude in her absence; nor is her return greeted with that congratulatory tenderness that so eminently characterises the males of other birds. The male proffers the same civilities to any female indiscriminately, and they are reciprocated accordingly, without exciting either resentment or jealousy in any of the party. This want of sexual attachment is not inconsistent with the general economy of this singular bird; for, as they are neither their own architects nor nurse of their own young, the degree of attachment that governs others would be superfluous. \* \* \*

"By a minute attention to a number of these birds when they feed in a particular field in the laying season, the deportment of the female, when the time of laying draws near, becomes particularly interesting. She deserts her associates, assumes a drooping, sickly aspect, and perches upon some eminence where she can reconnoitre the operations of other birds in the process of nidification. If a discovery suitable to her purpose cannot be made from her stand, she becomes more restless, and is seen flitting from tree to tree, till a place of deposit can be found. I once had an opportunity of witnessing a scene of this sort, which I cannot forbear to relate:—Seeing a female prying into a bunch of bushes in search of a nest, I determined to see the result, if practicable; and knowing how easily they are disconcerted by the near approach of man, I mounted my horse and proceeded slowly, sometimes seeing and sometimes losing sight of her, till I had travelled nearly two miles along the margin of a creek. She entered every thick place, prying with the utmost scrutiny into places where the small birds usually build, and at last darted suddenly into a thick copse of alders and briers, where she remained five or six minutes, when she returned, soaring above the underwood, to the company she had left feeding in the field. Upon entering the covert, I found the

nest of a yellow-throat" (*Trichas personatus*), "with an egg of each. \* \* \* In the progress of the cow-bird along the creek's side, she entered the thick boughs of a small cedar, and returned several times before she could prevail on herself to quit the place; and upon examination, I found a" species of "sparrow sitting on its nest, into which she no doubt would have stolen in the absence of its owner." We may have occasion to refer to these observations when we give the natural history of the European cuckoo.

"The deportment of the yellow-throat on this occasion is not to be omitted. She returned while I waited near the spot, and darted into her nest, but returned immediately and perched upon a bough near the place, remained a minute or two and entered it again, returned and disappeared. In ten minutes she returned with the male. They chattered with great agitation for half an hour, seeming to participate in the affront, and then left the place. I believe all the birds thus intruded upon, manifest more or less concern at finding the egg of a stranger in their own nests. Among these, the sparrow\* is particularly punctilious, for she sometimes chirps her complaints for a day or two, and often deserts the premises altogether, even after she has deposited one or more eggs." Many small birds will indeed eject an alien egg from the nest. "The following anecdote will show, not only that the cowpen finch insinuates herself slyly into the nests of other birds, but that even the most pacific of them will resent the insult. A blue-robin had built for three successive seasons in the cavity of a mulberry tree near my dwelling. One day, when the nest was nearly finished, I discovered a female cow-bird perched upon a fence stake near it, with her eyes apparently fixed upon the spot, while the builder was busy in adjusting her nest. The moment she left it, the intruder darted into it, and in five minutes returned and sailed off to her companions with seeming delight, which she expressed by her gestures and notes. The blue-bird soon returned and entered the nest, but instantaneously fluttered back with much apparent hesitation, and perched upon the highest branch of the tree, uttering a rapidly repeated note of complaint and resentment, which soon brought the male, who reciprocated her feelings by every demonstration of the most vindictive resentment. They entered the nest together, and returned several times uttering their uninterrupted complaints for ten or fifteen minutes. The male then darted away to the neighbouring trees, as if in quest of the offender, and fell upon a cat-bird," (*Orpheus felivox*), "which he chastised severely, and then turned to an innocent sparrow that was chanting its ditty in a peach tree. Notwithstanding the insult was so passionately resented, I found the blue-bird had laid an egg the next day. Perhaps a tenant less attached to a favourite spot would have acted more fastidiously, by deserting the premises altogether." We know, indeed, from direct experiments, that when the egg of a stranger is placed into a nest before any of the owner's eggs had been deposited, the nest is most usually forsaken.

Some interesting observations follow, upon the nature and disposition of the various birds into whose nests the cow-bird's egg is commonly deposited, with some remarks on the curious fact, that the eggs of the owner of the nest are never hatched, as those always are which accompany the cuckoo's egg. We need

not here transcribe all the detail of facts that is given, but will come at once to the writer's conclusion. "How do the eggs get out of the nest? Is it by the size and nestling of the young cow-bird? This cannot always be the case; because, in the instance of the blue-bird's nest in the hollow stump, the cavity was a foot deep, the nest at the bottom, and the ascent perpendicular; nevertheless the eggs were removed, although filled with young ones; moreover a young cowpen finch is as helpless as any other young bird, and, so far from having the power of ejecting others from the nest, or even the eggs, that they are sometimes found on the ground under the nest, especially where the nest happens to be very small. I will not assert that the eggs of the builder of the nest are never hatched; but I can assert, that I have never been able to find one instance to prove the affirmative. If all the eggs of both birds were to be hatched, in some cases the nest would not hold half of them; for instance, those of the sparrow, or yellow-bird. I will not assert that the supposititious egg is brought to perfection in less time than those of the bird to which the nest belongs, but, from the facts stated, I am inclined to adopt such an opinion. How are the eggs removed after the accouchement of the spurious occupant? By the proprietor of the nest unquestionably; for this is consistent with the rest of her economy. After the power of hatching then is taken away by her attention to the young stranger, the eggs would be only an incumbrance, and therefore instinct prompts her to remove them. I might add, that I have sometimes found the egg of the sparrow, in which were unmatured young ones, lying near the nest containing a cow-bird, and therefore I cannot resist this conclusion. Would the foster parent feed two species of young at the same time? I believe not. I have never seen an instance of any bird feeding the young of another, unless immediately after losing her own. I should think the sooty looking stranger would scarcely interest a mother, while the cries of her own offspring, always intelligible, were to be heard. Should such a competition ever take place, I judge the stranger would be the sufferer, and probably the species soon become extinct. Why the *lex natura conservatrix* should decide in favour of the surreptitious progeny is not for me to determine."

It will be seen upon a reference to our article Cuckoo, that the ingenious writer was wrong in some of these suppositions. We need not, however, here forestall our account of the various facts which we have to give concerning that interesting bird; but proceed now to copy Wilson's description of a cow-bunting, which he reared in confinement, and must then conclude our long account of this very singular species. "In the month of July, I took from the nest of the Maryland yellow-throat, which was built among the dry leaves at the root of a brier bush, a young male cow-bunting, which filled and occupied the whole nest. I had previously watched the motions of the foster parents for more than an hour, in order to ascertain whether any more of their young were lurking about, or not; and was fully satisfied that there were none. They had, in all probability, perished in the manner before mentioned. I took this bird home with me, and placed it in the same cage with a Red-bird," (or Cardinal grosbeak, *Guirica cardinalis*), "who, at first, and for several minutes after, examined it closely, and seemingly with great curiosity. It soon became cla-

\* A very different bird from the sparrow of northern Europe.  
NAT. HIST.—VOL. II.

morous for food, and from that moment the red-bird seemed to adopt it as his own, feeding it with all the assiduity and tenderness of the most affectionate nurse. When he found that the grasshopper which he had brought it was too large for it to swallow, he took the insect from it, broke it in small portions, chewed them a little to soften them, and with all the gentleness and delicacy imaginable, put them separately into its mouth. He often spent several minutes in looking at it, and examining it all over, and in picking off any particles of dirt that he observed on its plumage. In teaching and encouraging it to learn to eat of itself, he often reminded me of the lines of Goldsmith—

“He tried each art, reprov’d each dull delay,  
Allur’d to ‘fav’rite food,’ and led the way.”

The sight, however, of a young helpless nestling operates wonderfully upon the instinctive feelings of most birds, however dissimilar may be the species, of which a very striking instance has been already given in our article BOTTLETT.

“This cow-bird,” continues Wilson, “is now six months old; is in complete plumage; and repays the affectionate services of his foster-parent, with a frequent display of all the musical talents with which nature has gifted him. These, it must be confessed, are far from being ravishing; yet, from their singularity, are worthy of notice. He spreads his wings, swells his body into a globular form, bristling every feather in the manner of a turkey cock, and, with great seeming difficulty, utters a few low spluttering notes, as if proceeding from his belly; always, on these occasions, strutting in front of the spectator with great consequential affectation.

“To see the red-bird, himself so excellent a performer, silently listening to all this guttural splendour, reminds me of the great Handel contemplating a wretched catgut-scraper. Perhaps, however, these may be meant for the notes of *love* and *gratitude*, which are sweeter to the ear, and dearer to the heart, than all the artificial solos or concertos on this side heaven.”

Here we cannot but remark that the males of nearly all sorts of polygamous birds exhibit some sort of curious display in uttering their notes. Thus, the grouse (*Tetrao*), spread their tails and strut, whilst the nearly allied, but monogamous, ptarmigan (*Lagopus*), do nothing of the kind. Almost all birds that spread out their plumage, like the peacock and turkey, are polygamous. Indeed, birds that never pair are generally distinguished by supernumerary feathers, or by having particular parts of their plumage unusually produced. Thus, the Ruff (*Machetes pugnax*) is the only known species of the sandpiper and plover tribes which is polygamous; and it is the only one which is distinguished in summer by a remarkable development of feathers about the head and neck. So the bitterns are the only known polygamous birds of the heron kind, and these are similarly distinguished. The bustards also are polygamous, and the males of these have accessory plumage in summer; and common poultry are polygamous, the males of which have many feathers of their much produced. But the rule does not invariably obtain: many pheasants and polygamous species of ducks exhibit no kind of display; and the monogamous partridges are not thus to be distinguished from the polygamous quails; and inversely, in certain humming-birds and others, which are known to pair, the males have a very splendid display. The rule, however, is sufficiently general to allow of its being worthy of remark.

COW-PARSNEP is the *Heracleum sphondylium* of Linnaeus. This is one of our largest herbaceous plants, and known by the provincial name of kex or kexes. It is very common in damp meadows, and as its seeds are always shed when hay is made, it is liable to usurp too much room in the turf. Grazing the meadow for a few consecutive years is the best way to get rid of it, because the leafy point of the stems is nibbled off by the sheep as soon as they shoot up. It is a very coarse plant in hay, though it does not appear to be ungrateful to cattle. Cow-parsley is another *Heracleum*, but which is a native of Siberia.

COWSLIP is the *Primula veris* and *vulgaris* of Linnaeus. If any one plant is better known than another it is this; every child knows the cowslip; and notwithstanding its being so common, and in favourable spots in such great profusion, it is always welcomed and admired. There are several unnoticed varieties of this plant; and it is allied to a numerous family, of which the auricula, polyanthus, and primrose are the chief; all which are described under the proper names, and in that of the natural order to which they belong. A kind of wine is made from the flowers of the cowslip, which, it is said, is particularly efficacious as a febrifuge.

CRAB. The ordinary English name by which many of the larger species of the crustacea are distinguished, and to which in the Linnaean system the name of *Cancer* was applied. The term however is not exactly synonymous with the latter name, as the lobster, cray-fish, shrimp, prawn, &c., formed portions of the Linnaean genus. Since the time of Linnaeus, however, the study of these animals has greatly increased, so that the two Linnaean genera, *Cancer* and *Monoculus*, have been raised to the rank of a distinct class composed of several orders, one of which, the *Decapoda*, or ten footed crustacea, comprises two principal divisions, the *Brachyura*, or those of a broader form and with short tails, and the *Macroura*, having an elongated form and a more developed abdomen. In the former division, the animals known by the ordinary name of crabs are placed, whilst the latter comprises the other species above mentioned; still, as if to show the total disagreement of the ordinary terms in natural history with their scientific limits, the king crab of the tropical seas belongs to a totally different order of crustacea than either of those above mentioned, whilst even the hermit crab belongs to the *macroura*.

Crabs are for the most part marine animals, frequenting the rocky shores of the ocean, and having the body generally broader than long, although in a very few instances the reverse takes place. As, however, the general structure of the crabs will be found detailed under the article BRACHYURA, we shall here confine ourselves to a few general observations upon the habits of the order. We regret their paucity, owing as it is to the very slight attention which has been paid to the habits of marine animals.

This class of animals, as compared with that of the true insects, is very limited in its extent, but many of the species far exceed in size any of the great division of annulose or ringed animals, whilst some of them are very minute. They are found in all latitudes, but are more abundant in the warm and temperate climates than in more northern regions. Some genera, as *Ocypode*, *Gecarcinus*, *Uca*, *Grapsus*, &c., frequent more southern regions, being found in nearly equal latitudes in the different parts of the old and new

world. Others, as the true crabs, *Portunus*, &c, are more generally distributed, extending from the equator to the polar circles.

The local habitations of these animals are, however, very varied. Some few species of crabs penetrate to a considerable distance inland, but are compelled to return to the sea at the period of coupling and oviposition. Other species, although having the form of the marine crabs, do not quit the fresh water, as in the *Telphusa*. Again, amongst the marine species, the majority do not quit the shores, whilst others are found at great distances in the high seas, where they can rest only on the floating banks of sea-weeds so abundant in the tropics. And even in those species which frequent the coasts, the same situations are not congenial to them all; some, as the *Dorippe* and *Inachi*, reside at great depths of the sea, from two to four hundred feet, whilst others keep continually at the surface of the waters, passing a great part of their existence upon the shores continually washed by the waves. Some species, again, frequent only the rocky parts of the coast, abounding in madrepores and difficult of access, whilst others prefer sandy shoals, in which they bury themselves.

Amongst the land crabs some species, as the *Ocypode*, make deep burrows, at the mouth of which they ordinarily take their station after the fashion of sentinels, whilst some, as the *Ranina*, prefer more elevated places, and sometimes even mount the roofs of the huts of the Indians. The crabs are, moreover, the most active animals of the class with reference to their powers of walking, although the *Macroura* certainly excel them in swimming. In those crabs which run fastest the eight hind legs are alone employed, and are terminated by strong pointed hooks. They walk with the same facility, forwards, backwards, and from side to side, indeed in all possible oblique directions. They will also ascend inclined planes, and even almost perpendicular surfaces, provided these planes be not quite smooth. Many, as the *Ocypode* and *Geometra*, are noted for their rapidity in running; indeed it is said that a man at full speed would be unable to overtake them. Many species of crabs walk with much less agility than the others, being more decidedly aquatic. They are therefore provided with dilated legs, having the margins furnished with rows of hairs, which are thence converted into natural oars, and by the assistance of which these species are able to perform the same motions in the water as the others do on the shore, and in equally varied directions. Such are the *Podophthalmi*, *Matuta*, *Portuni*, &c., which have hence acquired the name of shuttle crabs, *Cancer vocans*.

Crabs are in general very courageous, and when their retreat is cut off they stretch out their claws, and endeavour to nip with them, which they do with much force, owing to the size of these parts. Some species, in shutting these claws with violence and rapidity, produce a strong sound; and as they hold their claws in the air with which they make this noise, they have fancifully obtained the name of Calling Crabs.

Crabs, as well as the generality of the class *Crustacea*, feed upon animal matter, especially when in a state of decomposition. Dead bodies, floating upon the surface of the waves, or cast upon the shore by them, are immediately covered with these animals, and there is every reason to suppose that they are attracted by their powers of scent, although the seat

of this sense is not known. Some of the carnivorous crabs even attack living prey, and fight fiercely in order to procure it. In these combats they often lose their claws, which are however soon reproduced, but they never attain the same size as previously. This reproduction of the limbs is one of the most curious circumstances connected with the class, and respecting which we shall give further details in our observations upon the class. In like manner we shall reserve the account of the transformations which these animals have recently been asserted to undergo by Mr. J. V. Thompson, in his valuable *Zoological Researches*, as well as an account of the periodical moulting undergone by them.

**CRABRO** (Geoffroy). A genus of hymenopterous insects synonymous with *Cimbex*.

**CRABRONIDÆ** (Leach). A family, or perhaps rather a sub-family, of hymenopterous insects belonging to the section *Aculeata* and subsection *Fossoræ* or false wasps. The head is large and nearly square, seen from above; the antennæ often gradually thickened at the tips; the abdomen oval or elliptic, broadest at the middle, or narrowed at the base into a peduncle. The insects introduced into this family may be divided into two distinct sections with reference to their natural habits, which are very interesting: first, the true burrowers, which form their own nests, either in the sand or in decayed rotten posts, and similar situations; these have the fore-legs in general armed with strong spurs to enable them to perform their laborious operations in the construction of their nests; and, secondly, the species which are destitute of these spurs, and which consequently being unable to make their own nests, deposit their eggs in the nests of the other species, and in which the parent fly has already deposited a supply of food consisting of other insects, upon the bodies of which, as well as also (in all probability, although the point has not yet been decided) upon the real inhabitant of the cell, the larvæ hatched from the eggs thus surreptitiously introduced into the cells feed. The genera are, *Trypoxylon*, Latreille, which provisions its nest with small spiders; *Gorytes*, which are considered parasites; *Crabro*, which generally burrow in wood, and provision their nests with the caterpillars of small moths found upon the oak, as well as with dipterous flies\*. Some of the male have the anterior tarsi dilated into a curious circular plate; *Stigmus* and *Pemphredon*, which burrow in sand, one of the species of the latter burying numbers of plant lice for the food of her future progeny; *Mellinus*, *Alyson*, *Psen*, *Philanthus*, the larva of which is supplied with bees; and *Cerceres* (which see for a more detailed account of the habits of the last two genera).

**CRAMBE** (Linnæus). A genus of herbaceous perennials, one of them a native of Britain, and known by the name of sea-kale. These plants belong to the class *Tetradynamia*, and natural order *Crucifera*. Sea-kale is found wild on sandy shores, and as it rises with large succulent shoots and unexpanded leaves early in the spring, had been long used as a substitute for young cabbage by the country people in those places where it was plentiful. Near four-score years back it was brought, though partially, into garden culture; but was in little esteem till about

\* We have just noticed one of the species of this genus flying along with a crane fly, larger than itself, the legs of which it had previously cut off.

1794, when being then found to be no bad substitute for forced asparagus, particularly at the best tables in the city of Bath, it came suddenly into high repute, and consequently has been extensively cultivated ever since as well in public as in private gardens. The ease and certainty with which it may be forced, so as to have a regular supply throughout the winter, is an additional recommendation, and especially, as it is found to be a suitable supper dish for persons of weak constitutions, and who cannot, at that meal, partake of any kind of animal food.

The plant may be grown luxuriantly in any soil, provided it is loose enough; but its excellence, as a condiment, depends not on its bulk, but on its mild flavour, and therefore means must be taken to grow it in the poorest soil, even pure sand, in order that the naturally rank cabbage flavour may be corrected.

Sea-kale is usually cultivated on beds or borders in any open part of the garden. The body of the bed may be composed chiefly of sea or river sand, to the depth of twelve or fifteen inches. The surface of the bed may be four or five inches lower than the general level of the ground when the seeds are sown or when roots are planted, and then covered with an inch of pure sand. When seeds are used, they are dropped along the middle of the bed in patches, two feet from each other, three or four good seeds together. If they all rise, reduce to two or three at each place, and in the future management, it should be endeavoured to keep the crowns of the plants always as low and near together as possible, for the purpose of covering them with pots or otherwise, when necessary.

The roots, particularly on the upper parts, are thickly studded with buds, so that, notwithstanding the annual loss of the crowns, other shoots are soon afterwards produced from below. This peculiar property of the roots renders a new plantation of sea kale easily made, and which will come as soon into use as if seed had been sown. Either method may, therefore, be followed; and before the winter sets in, the plants will have arrived at a considerable size. All the shoots have a tendency to rise, and the crowns which are to be relied on for the following year's crop, will remain an inch or two higher than the surface after the leaves are shed. This circumstance requires that the crowns be covered with an additional layer of sand, through which the young eatable shoots will protrude in the spring of the following year. If it be wished to have any strong stools, refrain from cutting any in the second year; but if the plants have grown vigorously the first year, a few dishes may be taken without injury.

Many schemes have been practised to induce an early growth of the shoots, because, if the kale do not come in before asparagus, it will be but little esteemed. Deep coverings of pure sand, of coal culm, of decayed light dung or leaves of forest trees, to the depth of a foot or more, have all been used with various success. One of the most common modes is covering the crowns with large garden flower pots, and heaping around and upon these, a ridge of hot stable dung that has been previously prepared by frequent turnings to dissipate the rank steam and heat. The heat imparted from the covering excites the plants into action, and by this means sea-kale may be had in any of the winter or spring months, provided the heating substance be applied seven weeks before the kale is wanted.

Other and equally efficient plans for forcing the crop have been executed. Single rows of plants are put in along the middle of two-foot-wide beds, having two-foot-wide alleys between. The alleys are dug out to the depth of eighteen inches, and the sides of the beds are kept up by open or pigeon-holed brick-work. Six or seven weeks before the kale is wanted, any required length of the beds have the alleys filled with hot dung, and the crowns being covered with pots, hand glasses, or wooden troughs, made for the purpose, and covered over the crowns with additional coverings of mats in severe weather, brings up the shoots expeditiously and in their *purest* state, neither tainted by the effluvia of the dung, nor discoloured or soiled by any matter in contact with them. Neither air or light are necessary to the shoots; perfect blanching not only improves its appearance when dressed, but its flavour also in a considerable degree. It may be repeated, that its excellence entirely depends on the poverty of the soil in which it is grown, and its perfect etiolation. Sea-kale may be raised on very rich soil and of very great size; but few ladies could sit at the table on which it is served up.

But this plant may be conveniently forced in pots, either in a hot-house, hot-bed, or even in any warm corner of a kitchen. Large pots are filled with stout roots among light earth or sand; another pot of the same size is inverted over the first; in this dark prison the shoots are produced, equal in delicacy, though not in quantity, as they can be by any other means. The proper temperature for sea-kale experience has taught is about 55° of Fahrenheit.

**CRAMBUS** (Fabricius). An extensive genus of small lepidopterous insects, respecting the family of which there is some uncertainty, Mr. Stephens placing them in the *Tineidae*, Mr. Curtis in the *Pyralidae*, and Latreille forming them into a family termed *Grambites*. They are very active, abounding in pastures, and amongst grass, upon the stalks of which they generally rest with their heads downwards and their wings very closely applied, in a convoluted manner, to their bodies, so that they were originally termed close-winged moths, their appearance being nearly that of a cylinder. They take flight very readily at our approach, but soon settle again. The upper wings are long and narrow, their antennæ simple, the labial palpi are stretched forwards, the maxillary spiral tongue is long and slender, and the maxillary palpi very distinct and raised in front. There are nearly forty British species, including the type *Phalaena Pascuella*, Linnaeus. Some of them are so exceedingly abundant that scores are disturbed in certain situations at every step. We do not remember ever to have met with them in such abundance as in the month of August on the exposed sides of the Hill of St. Catherine, at the back of the Isle of Wight. Their colours are pale, and they are often ornamented with silvery markings.

**CRANBERRY**, is the *Oxycoccus Palustris* of Persoon, and the *Vaccinium Oxycoccus* of Linnaeus, a common British plant, found on turfy bogs. The fruit of this plant is very generally employed as a kitchen article for tarts. Both the British and American long-fruited cranberries are gathered for sale, and large quantities are annually imported from North America.

The late Sir Joseph Banks advised the garden culture of the American species, and several gardeners have been extremely successful in the attempt. Much

depends on the possession of a suitable site to grow the cranberry. A piece of turfy bog, by the side of a pond, is the natural situation; or an artificial border of bog-earth may be formed, on which there may be no fear of the plant succeeding. This latter project, however, can only be justified by comparing the cost of home-growth with that charged by the retailers of the fruit in this country.

CRANE FLY, one of the names by which the larger species of the dipterous insects belonging to the family *Tipulidæ* are generally termed; they are also called daddy long legs, tailors, &c. They are very abundant in pastures, especially at certain seasons of the year, as at the end of the summer, when they rise in swarms on being approached. Their long legs are of great service to them in enabling them to make their way through the long grass, but these limbs are so slightly attached to the body, that they fall off at the least touch, and the insect flies off, leaving them in the hand when seized, with as little apparent care as though nothing had occurred. Now if this violent deprivation of the limbs were to happen in the higher animals, what would be the result? Is it not certain that death would be the result? And is it not equally clear, that as this does not occur with the insect, that the general construction of the two sets of animals is so completely distinct, that it is impossible for us to judge with precision as to their feelings or senses, which, in all probability, (may we not rather say, absolutely necessarily,) are quite distinct from our own?

The long legs of these insects are likewise very useful to them at the period of depositing their eggs, at which time the body is carried in a perpendicular position, supported by the legs; the abdomen is terminated by an acute point formed of two horny spines, between which the eggs are protruded. This ovipositor is thrust by the insect into the earth, in which the eggs are placed, and as each female lays several hundred eggs, it is curious to see it when engaged in this operation, raising its body up and down, laying an egg each time its tail touches the ground. In this manner it proceeds for a considerable space without ever assuming an horizontal position. The larvæ hatched from these eggs are fleshy grubs without legs, having the mouth furnished with two jaws, and several other organs, and the tail armed with several spines. These larvæ are very injurious by attacking the roots of the herbage, amongst which they have been hatched, and causing the plants to die. And as the eggs are placed so close together, it is not surprising that the larvæ are exceedingly numerous, when this is the case, the whole surface of the ground is of course entirely stripped. When these larvæ have attained their full size, they are transformed into quiescent pupæ, which, previous to assuming the perfect state, perform the same manœuvre of pushing part of their bodies above the surface of the earth, just as we have described the proceedings of the cossus, the cause of which is the same in each case.

CRANE'S BILL is the *Geranium* of most authors. This well-known genus is found inhabiting the northern parts of Asia and Europe, with a few stragglers in North America and South Africa. Nearly twenty species are found in Britain, the principal part of which are herbaceous perennials. Many are ornamental, but none are useful; at least their virtues are unknown. See GERANIUM.

CRANGON (Fabricius). A genus of crustaceous

animals, belonging to the order *Decapoda*, section *Macroura*, and family *Palemonidæ*, having for its type the common edible shrimp (*Cancer Crangon*, Linnaeus; *Crangon vulgaris*, Fabricius). The two anterior legs are terminated by a moveable claw; the second pair of legs are didactyle, slender, and rather longer than the preceding; the rostrum of the shell is short, and the shell itself smooth; the abdomen is rounded; the wrists not annulated, and the legs not provided with a basal appendage. There are several species of this genus, but the most common and best known is that above mentioned, and which is found in great profusion swimming in shoals near the shores with great agility upon their backs. Immense numbers of them are eaten, especially by the inhabitants of the western coasts of Europe. They are caught by means of a large open net, held at the end of a long stick, by women and boys, upon our sandy shores. They are also employed as a bait for several kinds of fish.

CRANIA (Cuvier, Lamarck; *ANOMIA*, Linnaeus). Linnaeus included this in his genus *Anomia*, from which Bruguière first separated it, pointing out its distinctive characters. The shell is inequivalve, nearly round, and most generally affixed by its lower or inferior valve. The three indentations, or holes, which are on the internal surface of this valve, appear only to penetrate it, in consequence of the violence necessarily used to detach it from the substance to which it affixes itself by the external surface. Lamarck, therefore, does not consider them to be the apertures through which the animal protrudes certain muscles, in the manner of the *Anomia ephippium*, but merely depressions or cavities in the lower valve of the shell, while it remains closely adhering to any marine body. These holes or cavities give the shell the appearance of a human skull. In some respects it seems allied to the *Terebratulæ*, while the form of it, and being affixed by the inferior valve, would indicate an alliance with the genus *Orbicula*. The writer has seen this shell attached to the root of the red coral, but very rarely with both the valves perfect. In Sowerby's genera of shells, this genus is ably and very minutely described.

Another distinction between this genus and the *Orbicula* is, that the latter are only held in the fissures of rocks, or slightly adhere to them by some muscular fibres of the animal, while the *Crania* has the whole of one valve in immediate contact with the object to which it adheres.

The animal is not sufficiently known to be accurately described. The *Crania personata* is the only species of this genus known: it is so named from its resemblance to a mask. It is classed by De Blainville in the third class *Acephalophora*, first order *Paliobranchiata*.

CRASSATELLA (Lamarck; *MACTRA*, Gmelin). A great affinity exists between this genus of molluscs and those of the *Mastra* and *Lutraria*, it having, like them, the ligament of the valves internal, and attached to the primary cavities of each valve; but when closed, they fit exactly, and do not gape as in those genera. In some species the ligament is partially visible on the exterior, but less so than in the genus *Amphidesma*. The shells of this genus are generally thick and very ponderous—whence the name; they are striated longitudinally, denticulated, regular, subtriangular, equi-valve, inequilateral, the summits clearly defined, and evidently curved forward, the lunule and corselet very distinct; hinge very large, sub-similar, formed by two

cardinal teeth, divergent, separated by a deep cavity; two muscular impressions round, distant, united by the marginal ligula, without any trace of posterior sinuosity; the impression of the retractor muscle distinct. There are eleven species described, all from the Australian seas, and it is somewhat remarkable that many fossil species are found in France, and no where else.

**CRASSINA** (Lamarck; ASTARTE, Sowerby). In appearance this shell resembles a small crassatella, being thick and solid, the valves closing in every part, but it is distinguished from it by the position of the ligament. It cannot either be mistaken for a species of *venus*, since, on a comparison, it is found to possess not more than two teeth on each valve, and even appears to have but one, very large, on the left valve, the other projecting but slightly. The shell is orbicular, transverse, equivalve, sub-inequilateral, and closed. Hinge with two divergent teeth, and two on the other very unequal. Ligament external, and placed on the longest side. The name of this genus has been properly changed by Sowerby, several species of this mollusc having been described under that name, previously to Lamarck's adopting that of *crassina*, a circumstance he either overlooked or was ignorant of. The *Venus Danmoniensis* of Montague illustrates this genus.

**CRASSULA** (Linnæus). An extensive genus of greenhouse succulents, natives of the Cape of Good Hope, Linnæan class and order, *Pentandria Pentagynia*; and natural order, *Crassulaceæ*. Generic character: calyx tubular, and five-parted; petals connected at the base, and bearing the stamens; five nectariferous scales below the germen; seed-vessel five-pointed, bursting inwardly, many-seeded. The *crassulas* are mostly what are called under, or half shrubby plants, with thick fleshy leaves, and many of them bear showy flowers. Like all other succulents, they thrive best in a dry soil, mixed with lime rubbish, to allow of water draining quickly away from the roots. Cuttings strike readily, if allowed to dry for a day or two after they be cut, that the fresh wound may be somewhat dried before placing in the soil.

**CRASSULACEÆ**—the house-leek family. A natural order of dicotyledonous or exogenous plants, containing nineteen known genera, and nearly three hundred species. In its succulent stem and leaves this order resembles *Cactææ* and *Portulacææ*. It bears an affinity to *Saxifragææ* and *Illecebreææ*, but differs from these orders in its hypogynous scales. There is no instance of a double flower in the order.

Its essential characters are: sepals from three to twenty, more or less united at the base; petals equal to them in number and alternate with them, inserted into the bottom of the calyx; stamens inserted with the petals, either equal to them in number and alternate with them, or twice as many, those opposite the petals being shortest; filaments distinct, awl-shaped; anthers of two cells bursting longitudinally; a hypogynous nectariferous scale at the base of each ovary; ovaries of the same number as the petals, opposite to them, placed in a circle, distinct, one-celled, tapering into stigmas; several one-celled carpels opening longitudinally and internally; seeds attached to the margin of the suture, varying in number; albumen thin, fleshy; embryo straight; radicle turned towards the hilum.

The plants belonging to this order are succulent

herbs or shrubs with fleshy entire, or pinnatifid leaves, and sessile cymose flowers which are often unilateral

They are found most abundantly at the Cape of Good Hope. They are also met with in Europe, North and South America, Siberia, the East Indies, and New Holland. None of the species inhabit the West Indies. They grow on dry arid situations, such as naked rocks, old walls, and sandy plains, where there is scarcely any other kind of vegetation. They imbibe nourishment by their whole surface, and do not depend for it on the soil in which they grow. In their properties they are refrigerant, and sometimes acrid.

The chief genera of the order are, *Crassula*, *Sempervivum*, *Sedum*, *Cotyledon*, *Umbilicus*, *Tillæa*, *Globulea*, *Rochea*, and *Rhodiola*.

Of the genus *Crassula* there are several species, some of which are cultivated in our greenhouses on account of their beauty.

The genus *Sempervivum* (live for ever) derives its name from the tenacity of life which is exhibited by its species. *Sempervivum tectorum*, common house-leek, is frequent on the tops of cottages in this country, and is often regarded by the country people with feelings of veneration: Its leaves are cooling and astringent, and when mixed with lard or oil are applied to burns, and wounds. They contain malic acid combined with lime. The fishermen of Madeira rub their nets with the *Sempervivum glutinosum* in order to render them hard and durable.

*Sedum telephium*, orpine, or live-long, is common on borders of fields and near hedges in Britain. It was formerly considered valuable as a vulnerary.

*Sedum acre*, biting stone-crop, or wall-pepper, is a common British plant. All parts of it are acrid and pungent. The expressed juice is emetic and purgative, even in small doses. The plant has been used as an antiscorbutic. In Germany it is applied to swellings of the joints, sometimes with considerable benefit. It is a plant which botanists find great difficulty in drying. It will continue to vegetate under great pressure applied at a high temperature. Its vitality must be destroyed by being dipped in boiling water before any attempt is made at exsiccation. The young shoots of *Sedum album* are boiled and used for food in some parts of France. *Sedum rupestre* and *reflexum* are cultivated in some parts of Holland and Germany for the purpose of being mixed with lettuce as a salad. The leaves of the *Umbilicus pendulinus*, wall pennywort, are applied externally as a cooling remedy. *Rhodiola rosea*, rose root, is so called in consequence of its large root, when dry, yielding a smell similar to that of roses. It is common on wet rocks in different parts of Britain, particularly on the Scottish mountains. It is sometimes cultivated in gardens, and is the badge of the clan Gunn.

**CRATÆGUS** (Linnæus) is the generic name of the well known hawthorn. It belongs to the twelfth class *Icosandria*, and to the natural order *Rosaceæ*. The species are mostly natives of the colder parts of America and Europe. The common hawthorn is one of our most beautiful wild shrubs, and universally used as a hedge plant, making an excellent fence, it being self-defended by its thorns, as well as by its stubborn and hardy constitution. There are six ornamental varieties of the common hawthorn, one or two of which bear red or crimson flowers, and which when

in bloom are most attractive objects. The fruit of some of the species, as the azarole, are esteemed in the dessert in the south of Europe, and many are cultivated as ornamental plants in shrubberies. The common sorts are propagated by seeds, the ornamental species by grafting on the common.

**CRATÆVA** (Linnæus). A genus of East and West Indian ornamental trees. The fruit of one species in the West Indies is called the garlic pear, from some similar quality. Linnæan class and order *Dodecandria Monogynia*, and natural order *Capparidææ*. Generic character: calyx of four sepals, deciduous; petals clawed, limb often deflexed; stamens inserted in a glandular disk surrounding the germen; filaments very long; anthers linear, and somewhat curved, margined at the base; germen on a long footstalk; style none; stigma sitting; berry many-seeded. These plants are kept in our stoves; thrive best in a rich soil, and are propagated by cuttings.

**CRATERINA** (Olfers; STENEPTERYX, Leach). A curious genus of dipterous insects belonging to the section *Pupipara* (or the order *Omaloptera* of Leach), and family *Hippoboscidææ*, or spider flies, and distinguished from *Hippobosca* by having the wings very long, and so narrow that it seems impossible that they can be employed by the insect as organs of locomotion. This family of insects is very curious both in their habits and structure. The females, instead of laying their eggs in the usual manner, retain them within the body, not only until the larva is hatched, but also until it has attained its pupa form, in which state it is deposited by the parent fly. These insects are parasitic upon various animals. The only species, however, of which the present genus is composed (*Hippobosca Hirundinis*, Linnæus), infests the swallow, and, from its large size and the number of individuals sometimes observed upon a single bird, it is evident that they cannot be otherwise than exceedingly troublesome, and even dangerous to this poor bird. The structure of the mouth is very remarkable; it is formed for suction, and comprises several acute bristles.

The nests of the swallow are also equally infested, the insects sucking the young birds as soon as hatched.

**CRAY FISH.** A crustacean animal, belonging to the order *Decapoda*, and section *Macroua*, and forming the genus *Potamobius* of Leach, although Desmarests and others unite it with the lobster in the genus *Astacus*. See *ASTACIDÆ*. An idea of this animal may be obtained from our figure.

Cray-fish.

The cray fish is found in the fresh waters of Europe and the north of Asia. It secretes itself under stones and in holes in the banks, from which it only comes forth to take its food, which consists of molluscous animals, small fishes, and decaying animal matter. It is said to attain to the age of twenty

years, its size gradually increasing all the time, as each year, at the end of the spring, it sheds its outer covering, shortly after which it is found encased in a fresh coat as firm as the old one, and much enlarged, sometimes having increased as much as one-fifth in its size.

The female deposits her eggs two months after impregnation, these she retains for a considerable time beneath her abdomen, keeping them in such situation by means of a viscid matter with which they are covered, and by which they are attached to the false, or swimming legs, with which this part of the body is furnished in its under surface. These eggs increase in size before the exclusion of the young, and are exceedingly numerous. The young ones, when hatched, are extremely soft and small, and entirely resemble their parent, beneath the abdomen of which they shelter themselves for several days. The flesh of this animal is much relished, and various medical properties have been attributed to it, which it is very questionable if it really possesses. It has been remarked, that those which are caught in clear and running streams are of a better taste than those found in stagnant waters and in lakes. They are caught by sinking a net, or spiny faggots, in the middle of which a piece of putrid meat is placed. We well remember the delight with which, in our schoolboy days, we could escape the trammels of Bonnycastle and Virgil, and go groping, with our shirt-sleeves tucked up, in the holes in brooks where the cray fish were met with, and can therefore speak from experience of the sharpness of the bite which they can inflict with their claws. The tops of their claws were, in bygone times, employed in medicine, being considered as a valuable absorbent when pounded. Their place is now supplied in our pharmacopœias by the carbonate of magnesia.

**CRENATULA** (Lamarck; *OSTREA PICTA*, Gmel.). This mollusc constitutes a very remarkable genus, somewhat resembling the *Mytilus*, but by the great similarity of the hinge it seems more nearly allied to the *Perna*. There is, however, even here a distinct and peculiar difference; the hinge of the crenatula is composed of slightly concave callous crenulations, whence its name. These receive the ligament, while in the *Perna* the hinge consists of parallel truncated linear teeth, or rather rib-like joints corresponding and opposed to the opposite ones, the ligament being inserted only at their interstices. Shells of this genus are thin and extremely delicate; of a foliated texture, resembling the *Placuna*, *Avicula*, and similarly constructed molluscs, more or less irregularly formed; the valves are flattened, foliaceous, and no distinct opening for the byssus; the summits anterior, gaping backward; one muscular impression only, which is subcentral.

The animal is not yet described, but it properly differs but little from that of the *Perna*, which must be considered its immediate congener by analogous reasoning; seven or eight species are known in the different seas of hot countries, but the most part are found in Australasia.

De Blainville classes it in the third class *Acephalophora*, third order *Lamellibranchiata*, first family *Ostracea*.

**CREPIDULA** (Lamarck; *PATELLA*, Linnæus). This shell is one of the number of those confounded by Linnæus with the *Patella*, which it only resembles

in being apparently constantly fixed to one spot, as the form of their base assumes the shape of the substance to which they adhere; an examination of the animal, however, clearly distinguishes the genera. The shell is an oval or oblong, with a much depressed concave exterior, the spire inclined obliquely to one side, the margin entire, and the opening partially closed horizontally by a partition, giving it the appearance of a half-decked boat; some have angular longitudinal ribs on the surface, others have them armed with spines or prickles; they never possess an operculum, which marks a strong distinction between them and the *Navicula*. The portion of testaceous matter, partly closing the aperture, is placed between the mass of the animal's viscera and the posterior part of its foot. The muscular impression is in the form of a horse-shoe. A very natural association of species will be found as follows: such as have the shell thick, quite flat, and the summit not spiral, as in the *C. porcellana*, the next being nearly of the same form, but very thin and with an epidermis, and the last such as are nearly round, *C. garnotus*, and the summit subspiral, *C. subspirata*.

There are probably ten or twelve species described and about six fossil; they are of the second class *Paracephalophora*, third order *Scutibranchiata*, second family *Calyptracea*.

**CREPIDULINA** (Blainville; **CRISTELLARIA**, Lamarck). All the shells of this genus were united by Lamarck in his genus *Cristellaria*. The greater number of them are microscopic, and figured and described by Fichtel, who devoted much time and attention to these minute molluscs. The shell is oval, lengthened, a very small spiral summit; the last turn very ample, oval, nearly straight through its whole length, and closed by a diaphragm of the same form. The *Nautilus planatus* may be considered the type of the genus. Interesting as these small shells doubtless are, as illustrative of the connecting link in the great chain of relationship between the molluscous animals, and important as they must ever be as exhibiting in miniature all the same parts and functions as shells do of a gigantic structure, they nevertheless will only be valued by those who are anxious to investigate nature under every difficulty, and generally speaking to little advantage, since where one species admits of being seen by the power of ordinary optical instruments, there are thousands that are never seen at all but by the use of the most costly microscopes.

**CREPIS** (Willdenow). A genus of herbaceous uncultivated plants, mostly annuals, and mostly natives of Europe. The flowers are yellow, a good deal like those of the hawkweed, of course they belong to the natural order *Composite*.

**CRESCENTIA** (Linnaeus). A genus of West Indian trees remarkable for their large fruit. Linnæan class and order *Didymania Angiospermia*, and natural order *Solanacee*. Generic character: calyx in two parts, equal, deciduous; corolla, bell-shaped, bellying. limb two lipped, and of four or five lobes, upper lip short and crenated; stamens, rudiments of five; anthers two-lobed; style bearing a bilamellated stigma; fruit like a gourd, large, one-celled, many-seeded, no placenta; seeds compressed and round. This is called the calabash tree in the West Indies; the shell of the fruit being made into various kinds of vessels. The plants are in our collections, and chiefly valued for their fine foliage. They may be propagated by cuttings struck in moist heat.

**CREUSIA** (Leach). These molluscs, like the genus *Pyrgoma* of Dr. Leach, are the only two genera known to possess four valves, and the operculum to consist of two pieces only. Linnaeus classed them with his genus *Lepas*. They are in general small shells, affixed to madrepor or other marine substances, of an orbicular or conical convex form, composed of four unequal valves united, but distinctly marked by a suture at the divisions, the operculum bivalve and internal; a considerable calcareous support penetrating the substance to which the animal attaches itself. They belong to the family *Balanides*, and the animal partakes of the same functions. All the species of this family are so extremely singular and interesting, that it is much to be wished some naturalist, within reach of observing them in a living state, would direct his attention to a careful examination of these animals. In our opinion it would throw a very important light on the organisation of other molluscs, and those imperceptible gradations of change, so remarkable and so unaccountable in their structure, many of which may certainly be traced to necessity, but what has created that necessity, at present remains a mystery.

**CRICETUS**, hamster, a genus of rodent mammalia, resembling the rats in some particulars, but differing from them in many others. Their teeth are nearly the same, but their tail is short and covered with short hair, and their mouths are furnished with cheek pouches, in which they can carry a store of provisions to their subterranean retreat. The characters of this genus are: larger than the rat; reddish grey above; black in the flanks and underneath, with three white spots on each side; its fore feet are white, and there is also a white spot under the throat, and another under the chest. There are some individuals entirely black. This animal, so agreeably varied in colour, is one of the most hurtful which exists, in consequence of the quantity of grain which it gathers, and with which it fills its holes, which are at times nearly seven feet in depth.

The hamster is confined to the northern parts of the eastern world, and is most abundant in those places which bear a resemblance to the extensive plains to the westward of Rio de la Plata, in South America. In Europe, it is not found to the westward of the Rhine, but in proportion as the sandy plains are approached, it becomes more numerous. One can easily understand why this should be the case; and that it should be so, is a very wise provision of nature; for were hamsters abundant in the most fertile parts of the world, in those which are best adapted for cultivation, and, therefore, most valuable to man, such places would soon be rendered desolate, so rapidly do these animals increase in number, and so great are the ravages which they commit.

In a state of nature, the hamster partakes not a little of the ferocious disposition of the rat; and it has been alleged, that when in a state of confinement they have been known to prey upon each other, as is done by rats, moles, and some other burrowing animals. Still, however, the principal part of its food consists of vegetable matter, a store of which is laid up for at least part of the inclement half of the year, though the probability is that it hibernates the other half. It digs with great facility; each burrow it forms is composed of two entrances, one which conducts to an oblique canal, at the entrance of which the animal throws out and accumulates the earth which it is forced to remove, the other which serves as an exit to a vertical

canal, which is the true entrance to the burrow. These two canals conduct to a greater or less number of particular excavations of a circular form, which, according to the age of the animal, are from about one to five feet in diameter, and communicate together by horizontal conduits. One of these excavations is the retreat of the hamster; it is furnished with a good bed of dry herbs, and it is here that the females bring forth. The other excavations constitute the magazines of provision.

Every animal has its own burrow. The males have usually but two openings to theirs. The females form several by vertical conduits, especially when they have young ones. The burrows of the old individuals sometimes embrace a considerable extent; they descend to four or five feet in depth, and frequently contain many bushels of corn and other grain. They are sought out with great care; as much to collect what they contain, as to destroy the animals which form them, and which, when they are numerous, cause great devastation in the harvest. In the environs of Gotha, it is said, that in a single year eighty thousand of these have been killed; they are discovered by the quantity of earth accumulated at the entrance of their oblique excavation. These rodentia are not merely granivorous, they will also eat flesh, and often devour one another when they meet. Thus it is that, like the most ferocious animals, they live in a solitary manner, and never seek each other but at the season of love. The particulars of their reproduction are not precisely known. The rat, it would appear, takes place many times during the spring, summer, and autumn months; the gestation of the females lasts four weeks, and occurs three or four times in the year; there are usually from six to twelve young ones, which, after a very short lactation, quit the mother to go and dig, each for itself, a burrow, and live by their own resources. These notices apply to

The COMMON HAMSTER (*Mus cricetus* of Linnæus); but the animal is so numerous that a little more minute description may not be improper, and in the first place the characters of the teeth: of the three grinders with which each side of both jaws are furnished, the first in the upper jaw has three pairs of roots, and three pairs of tubercles divided by transverse furrows; the second has two pairs of roots, and two pairs of tubercles. The first in the lower jaw has five roots and five tubercles, and the two which follow in this jaw have four roots and four tubercles. The crowns of the teeth are, however, liable to be worn down with age; but, from their peculiar structure, and their numerous insertions into the jaws, the teeth of these little animals are very powerful for their size, so that they can readily bruise and divide the very hardest of vegetable substances. The eyes are rather small, very round, have a rounded pupil, and stand prominent. The ears are large, and rounded in the naked part. The nostrils open on the sides of a small muzzle, divided by a vertical furrow, which is prolonged across the upper lip; and the lower lip is so small that it scarcely covers the incisive teeth. The size is nearly the same as that of the brown rat, and the chief differences, except in colour, are, that the head is considerably larger, and the tail much shorter. The front, the upper part of the head, the sides of the body, and the upper part of the rump, are dull yellow, mixed with ash colour, the hairs being annulated with yellow and ash, and black at the points. The sides of the head and neck, the lower parts of

the flanks, the outside of the thighs, and the lower part of the rump, are reddish. The point of the muzzle, the lower part of the cheeks, and the feet, are of a very pale yellow, of which colour there are three large spots on each side of the animal. The throat, the breast, part of the fore legs, the inside of the thighs and legs, are deep maroon, passing into black.

There is something very remarkable in the accumulation of fat upon this animal. As it inhabits exposed and arid places, where but little rain falls during the summer months, it might be expected not to accumulate external fat, like the bears which live in covert, and the marmots which, as mountaineers, live near the snow, and are subjected to the variable weather of the alpine summer. But, contrary to the usual habits of animals which are understood to hibernate, the hamster is found with a much greater quantity of fat, internally, in the spring months than in the autumn.—This has been ascertained by direct observation of the most careful naturalists, who have had the best opportunities, and, therefore, it must be received as a truth; and, when along with this, we take into consideration the hoarding propensities of this animal, the argument against its hibernating is considerably strengthened. We believe, also, that few of the inhabitants of low and open places, have a hibernating character, though many of them keep to their burrows during the winter; and we have the evidence of hares and some other rodent animals in our own country, which do not lay up stores of provisions, as proofs that they are in best condition during the winter. The hamster digs its burrow to a considerable depth; and it is generally in soils which are sandy, or otherwise so formed as that the cold of winter does not penetrate them very deeply; and as, when the storm breaks, the transition is from cold to heat at once, without any of those prolonged contests between spring and winter which render more alpine climates so trying to animals, we may, perhaps, conclude that the hamster does not actually hibernate, though it remains in a state of inactivity, and thus not only exists but gets fat upon its accumulated store during the cold weather. In Siberia, during the months of March and April, when the temperature of the atmosphere was very cold, Pallas found that hamsters taken out of their holes had a heat of 103° of Fahrenheit's thermometer; and that others which were dug out from under the frozen earth, in the very depth of winter, had a temperature equal to that of the human body in health, or varying from 91° to 99°.

These are curious facts, and can hardly be reconciled with the notion of dormancy during the winter, although that were not doubtful upon the analogy above stated, that animals of the exposed plains are less exposed to hybernation than those which inhabit more sheltered places. As this is rather an important point, we shall lay before the reader, some of the evidences as derived from the observation of animals which are known to hibernate. The celebrated Hunter informs us, on the authority of Jenner, that the temperature of a hedgehog, in the cavity of the abdomen towards the pelvis, was 95°, and at the diaphragm was 97° of Fahrenheit, in summer, when the thermometer in the shade stood at 78°. Professor Mangili states the ordinary heat of the hedgehog a little lower, at 27° of Reaumur, or about 93° Fahrenheit. In winter, according to Jenner, the temperature of the air being 44°, and the animal torpid, the heat in the pelvis was

45°, and at the diaphragm 48½°. When the temperature of the atmosphere was at 26°, the heat of the animal in the cavity of the abdomen, where an incision was made, was reduced so low as 30°. The same animal, when exposed to the cold atmosphere of 26°, for two days, had its heat at the rectum elevated to 93°, the wound in the abdomen being so much diminished in size as not to admit the thermometer. At this time, however, it was lively and active, and the bed in which it lay felt warm. As the heat of this animal descended to 30°, when in its natural state of torpidity, and when there was no necessity for action, the increased temperature may in part be ascribed to the wound, which called forth the powers of the animal to repair an injury, which could not be done below its standard temperature.

Many similar experiments have been made, and the result of them all is, that the winter temperature of the hamster does not warrant the supposition that, however still it may be during the winter, it ever actually hibernates. For, contrary to what is the case with animals which do hibernate, the temperature of the hamster is as high at mid-winter, as that of the average of animals during the summer, and, indeed, higher; and, though the fact has not been sufficiently examined, it agrees with analogy that, with equal action, any animal should be warmer in winter than in summer; although the temperature of every animal will, of course, sink when that animal remains inactive.

That the temperature of this animal should have been found a few degrees higher in March and April, than it was earlier in the season, is no proof of coming from a state of dormancy, though it is a proof of some action; but the probability is, that this increase had a physiological cause, and was connected with the breeding of the animal. This part of the subject is however obscure, and we want a good deal of careful observation, before we can come to any just conclusion on the very important subject of the seasonal changes of temperature to which animals are subject, both on account of their own nature, and of the circumstances under which they are placed.

Throughout the wide range of territory which it inhabits, the hamster is subject to very considerable changes of colour; and, it should seem that, as it habits more northerly, it fades more into a white colour, and this, again, is in favour of its not being dormant in the winter.

Besides the common species, which is well known, and of which the fur is much used, though not very valuable, there are various smaller species described by Pallas and other naturalists, who have examined the northern parts of Eastern Europe and of Asia.—As the manners of these do not appear to differ much from those of the common species, our notice of them shall be brief.

**SAND HAMSTER** (*Cricetus arenarius*). This species is said to inhabit more to the southward than the other, and it is much smaller, not exceeding three inches and a half in length. It has the head oblong, the muzzle pointed; the extremity of the nose tumid, and reddish coloured; white mustachios, very furry, and longer than the head; lips very small; ears large, oval, and yellowish; all the upper part of the body of a pearl-gray colour; the under part, including the flanks, the feet, the tail, and even the claws, pure white. It inhabits the sandy plains, feeding on the roots of various plants which grow in these places, and also on the seeds of others. This is a nocturnal animal

*Cricetus accedula* is considerably smaller than the hamster. It has the nose rounded, and slightly covered with fur, divided by a furrow which also divides the upper lip. The lower lip, and angles of the mouth, are enlarged, and the cheek pouches are very large, extending down both sides of the neck, as far as the shoulders. The mouth, nose, and coverings of the pouches are white, the rest of the body greyish yellow on the upper part, and greyish white on the under. There are two or three other species, but they are small, and not of much general interest.

**CRICHTONITE**, a mineral of a velvet black colour, so named by Bournon in honour of Dr. Crichton. It occurs crystallised, usually of a very acute rhomboidal form, and is found in primitive rocks, along with octohedrite, in the different countries where that mineral is found.

**CRICKET**. The English name applied to several species of insects belonging to the order *Orthoptera* and family *Achetidae*. Thus the common house cricket is the *Acheta domestica*, the field cricket, *Acheta campestris*, and the mole cricket *Gryllotalpa vulgaris* (*Gryllus Gryllotalpa*, Linnæus). All these insects are evidently distinguished by the chirping creaking kind of noise which they produce, whence evidently the origin of the English name. It should be borne in mind, however, especially when consulting foreign works upon entomology, that the *cricquets* of the French authors are different from those of our own language; our crickets being by them commonly called *Grillons*, (and scientifically *Gryllus*, whereas they ought decidedly to bear the name of *Acheta*, being the Linnæan *Grylli Acheta*;) whilst the name of *Criquet* is given to the true locust family, the *Locusta* of the ancients, and the *Gryllus Locusta* of Linnæus. We cannot conceive why authors who have done so much for the science which they have so assiduously cultivated, should yet persevere in so evidently incorrect a nomenclature.

The cricket family is distinguished from the locust family, as well as from that of the grasshoppers, having long antennæ, by having the wings and wing-covers carried horizontally when at rest. The former extending beyond the latter in slender fillets, and the latter having a small circular space covered with a glassy membrane in the males, which is employed in producing the noise whence the insects have derived their name. As the females are destitute of this, they do not possess the power of chirping; the tarsi are composed of only three joints.

As the family *Achetidae* was omitted in its alphabetical situation, we have thus given its characters under the popular heading, rather than omit them altogether. The genera are by no means numerous, namely, the *Acheta*, *Gryllotalpa*, *Tridactylus*, and *Myrmecophila*.

In *Acheta* the legs are slender and formed only for running and leaping; the females are provided with a long and slender exerted ovipositor at the extremity of the body, and the antennæ are very long and slender.

The house cricket (*Gryllus domesticus*, Linnæus; *Acheta domestica*, Fabricius), is too well known to need much description. It is of a yellowish buff colour, varied with brown, and frequents the interior of our houses, especially where fire is continually kept, burrowing behind the chimney and grate, and multiplying in such situations to such an extent, that, independent of their disagreeable chirping (which, as

"de gustibus non est disputandum," is nevertheless liked by some persons), they become from their numbers a perfect nuisance, flying into the candles and dashing into people's faces, according to White. In families, at such times, they are like Pharaoh's plague of frogs, in their bed chambers, and upon their beds, and in their ovens, and in their kneading troughs. The strong chirping noise which the males make is occasioned by a brisk attrition of their wings, the glassy parts above mentioned acting like the parchment covering of a tambourine. This noise is chiefly produced at dusk, and during the night, although occasionally it may be heard during the day. The insect, however, is certainly a nocturnal one. As their presence in a house is regarded by some persons as ominous of ill luck, whilst others as firmly believe them to be prognostics of good, they may be especially referred to as a proof of the absurdity of those superstitious feelings which we trust the diffusion of knowledge is fast driving away. Their food, according to White, consists of crumbs of bread, yeast, salt, and any kitchen offal or sweepings. Latreille, however, says they thrive well in houses infested by cockroaches, upon which they feed, and they will certainly eat their own species when placed in confinement, but we should scarcely think this natural. They are very fond of moisture, preferring the moist mortar of new buildings; they will also gnaw holes in wet woollen stockings and aprons hung to dry; and one of the best modes of catching them is to place phials or other vessels half filled with beer, milk, broth, or the like, for being always eager to drink, they will crowd into the vessel and be drowned. They bring forth their young at all times of the year, as young ones may be found even in the winter months swarming on the hearth not larger than fleas.

The field cricket, *Acheta campestris*, is a much rarer animal than the former; it is of a black colour, with the base of the wing-covers yellow, the head is large, and the hind thighs red underneath. It burrows at the side of footpaths in hot situations exposed to the sun, making deep holes, at the mouth of which it sits, in order to seize upon stray insects which are its food.

The mole cricket is a curious animal, deriving its name from the similarity both of its structure and habits to the mole. The antennæ are short and slender, and the fore legs very broad and notched, being very powerful and well adapted for burrowing under ground; the abdomen is terminated by two long slender and hairy bristles. This insect, which, with some trifling variations in structure, is found all over the globe, is an inch and a half or two inches long, nearly cylindric, and of a brown colour.

It is a noxious animal, committing much injury in gardens and cultivated ground, burrowing a short distance beneath the surface, with the assistance of its large palmated fore legs. In this manner it loosens the roots of vegetables, upon which indeed it is said to subsist. Latreille however thinks, that it feeds upon underground insects or worms. The noise made by the male insect (and which is only heard during the night or at twilight), is said to be agreeable. The female forms in the month of June or July a subterranean chamber of an oval form, quite smooth internally, and about six inches deep, in which it deposits from two to four hundred eggs. The nest with its curved entrance somewhat resembles a flask with a bent neck. The young when hatched live for some time in society.

CRICOSTOMATA (genus *Turbo* of Linnæus). This is the name given to the second family of the second order *Asiphonobranchiata*, of the second class *Paracephalophora*. It may be observed that this family is scarcely to be distinguished from the Linnæan *Trochus*, which in fact is blended by almost insensible distinctions with his genus *Turbo*, and it is only, therefore, with a view of assimilating his labours as much as possible with the modern school, that the family *Cricostomata* has been established. This is only one of many instances which this work will exhibit of the veneration justly paid to that great naturalist's judgment, from which present authors presume not to differ, without pointing out conclusive reasons, and manifest cause for so doing.

A general description of these shells is, that they are of a variable form, but the aperture always nearly circular, and completely closed by a calcareous or horny operculum, the whorls of the spire few in number, and the summits sub-lateral.

The animal consequently is variable in form, but this applies rather to its exterior and some of its proportions, than in anything material in its organisation, which is the same in all the family. The animal appears always phytophagous; a small portion of them naturally breathe air, and the greater number of the aquatic species are marine. The various genera of this family will be noticed in their alphabetical arrangement.

CRINOIDEA. There is perhaps no result more extraordinary in the annals of modern research, than the discovery of the very remarkable and various changes which this our planet has evidently undergone, as indicated by the successive development and subsequent destruction of beings once animated, whose existence could never have been even suspected by us, had not their remains been still preserved in a fossil state. Whole tribes of animals seem to have been called into being, and after having for a certain period peopled the earth, appear to have gradually ceased to exist, in consequence of certain unknown causes which must for ever elude our inquiries, giving place to others of totally different forms, which in the course of subsequent ages were in like manner destined to pass away, their situations in the chain of animal life being replaced by other and possibly more perfect creatures, until we at length arrive at a point at which the inhabitants of this earth differed but slightly from the varied productions of the present time. Among these none are more remarkable than the remains now under consideration, not only on account of their curious forms, the beauty of their articulations, and the complicated nature of their structure, but also from their having evidently been among the earliest inhabitants of this world. Hence they are so far removed from the present order of animated nature, that although immense ranges of rocks may literally be said to be formed of the mineralised remains of different species entombed in them, but five or six fragments of one of these numerous species have hitherto been found in the recent state. Their fossil columns and joints, however, from their frequent occurrence and singular forms, attracted the notice of naturalists at an early period, and they consequently acquired names founded either upon certain superstitious ideas, or upon a fancied resemblance to other bodies, and the uses to which such bodies were applied. Thus we find them termed "giants' tears," "rosary beads," "fairy stones," "wheel stones," "entrochites," while the star shape of the

angular columns, occasioned them to receive the names *starstone*, *asteria*, &c.

By some these bodies were considered as inorganic filtrations, similar in their nature to stalactites. By others they were looked upon as the vertebral joints of fish, or as portions of some unknown species of coral. While others, who had more accurately observed the column and its termination, compared them to plants, whence they obtained the name of the stone lily, in consequence of the shape of the superior extremity of some of these remains, which very closely resembles a flower of that kind. They were at length considered as appendages to star fish, and were therefore supposed to have probably belonged to the *Asteria*, and as it was thought probable that they might yet exist in unexplored parts of the ocean, researches were anxiously set on foot to discover them in a living or recent state. At length a portion of an animal was found which bore a strong resemblance to the asterol columns so frequently found in the *Lias* and *Oolite*, and which, upon further investigation, appeared to possess an absolute identity of generic characters. Linnæus classed this species under his genus *Isis*, calling it *Isis asteria*. Lamarck, however, finding it did not agree in its characters with that genus, removed it to his genus *Encrinurus*, terming it *Encrinurus caput Medusæ*.

The fossils were however found to admit of at least two generic divisions, distinguished by the shape of the vertebræ. The one, the *Encrinurus*, having them chiefly of a cylindrical form, and the other, the *Pentacrinurus*, in which the vertebræ are principally pentagonal. Under these names, various species were formed, and which are described by Parkinson as the lily, cap, turban, stag's-horn, &c. encrinurites.

Since that time this family has been most ably illustrated by the researches of Mr. Miller, who, in his "History of the Crinoidea, or Lily-shaped Animals," has reduced these remains into genera and species, in the most satisfactory and scientific manner.

By him these numerous and interesting remains of animals of former times, which were before loosely described under the appellations of *Encrinurites* and *Pentacrinurites*, are classed as the members of one distinct and peculiar family, distinguished as the crinoidea, or lily-shaped animals. The members of this family are placed under four principal divisions, comprising nine genera, each containing several species, most of which were before that time very imperfectly described, and some of which were even utterly unknown.

The name *Crinoidea* is derived by him from a Greek word, signifying lily-shaped, and he defines the general character of this family as "an animal with a round, oval, or angular column, composed of numerous articulating joints, supporting at its summit a series of plates or joints, forming a cup-like body, containing the viscera, from whose upper rim proceed five articulated arms, dividing into tentaculated fingers, more or less numerous, surrounding the aperture of the mouth, situated in the centre of a plated integument, which extends over the abdominal cavity, and is capable of being contracted into a conical or proboscis shape."

In his first division, the joints, which form the inferior cup-like body of the animal, articulate with each other, whence the name *Articulata* given to this division, which contains three genera: *Apiocrinurites*, the pear-like lily-shaped animals, having two species;

*Encrinurites*, the true lily-shaped animals, containing one species; and *Pentacrinurites*, five-angled lily-shaped animals, comprising five species.

In the second division, the plate-like joints forming the cup, containing the viscera, articulate imperfectly with each other, from which circumstance it receives the name *Semi-articulata*. In this division he has but one genus, the *Pateriocrinurites*, or vase-like lily-shaped animal. Of these he describes two species.

His third division he names *Inarticulata*. In this the plates adhere by sutures, lined by muscular integuments.

These he divides into *Platycrinurites*, broad-plated lily-shaped animals, six species; *Cyathocrinurites*, or cup-like lily-shaped animals, four species; *Actynocrinurites*, or radiated lily-shaped animals, three species; and *Rhodocrinurites*, or rose-like lily-shaped animals, one species.

The fourth division contains those having the joints of the pelvis anchylosing to the first columnar joint; this has one genus, the *Eugeniocrinurites*, of which but one species was then known to exist.

Since the publication of Miller's work, many new genera have been discovered, many of the species have been subdivided, and the genus *Apiocrinurites*, in particular, has been very fully elucidated by the researches of J. Channing Pearce, Esq., F. G. S., who, in a highly interesting paper, "On the Oolite formation and its contents, as shown in a quarry at Bearfield, near Bradford," lately read before the Geological Society, but not hitherto published, has exhibited evidences of the most profound research and minute inquiry, joined to a close attention to the scientific arrangement of these bodies, highly creditable to his talents and observation; and as the information contained in that paper is perfectly new and also of great interest, some account of his labours may not prove uninteresting.

The first species of Miller, viz.: the *Apiocrinurites rotundus*, is the one to which the observations of this gentleman more particularly apply. This he proposes to divide into three species. He was led to form these distinctions from his peculiar advantages in living upon the spot where these remains are found in great abundance, and consequently being able to procure them in greater perfection than any collector had hitherto been enabled to do. In their generic description, he states them to be composed of a root or pedicle, from which rises a round column, having at the top a pear-shaped head, which supports arms and fingers, containing a series of cavities in their interior, which he considers as having contained the stomach and alimentary canal. The whole animal is composed of a vast number of flat joints or plates, which articulate with each other by lines radiating from the centre, which are, as it were, dovetailed into the next joint, and in like manner receive the radii of that joint. He supposes that they were covered externally with an epidermis, or skin, which was muscular, by the contraction of whose fibres, lateral motion in every direction was produced, by which means they were enabled to search for food, wherever it might be found within their reach. The root or pedicle consists of a number of concentric laminae, forming a cone, which surrounds the central column, the base being placed at the lower part, or at the point where the animal attached itself to rocks, &c., and, by forming a sort of buttress or support to the column, added very materially to its strength.

These plates appear to have been secreted from the edges of the joints, at the points of articulation with each other; and he mentions a specimen which, having been injured, exhibited this secretion actually going on in the form of little globules attached to many of the joints at their articulations, and he supposes that this animal, when injured in any part, performed the restorative process by exuding the matter in question in the manner just described. These pedicles are found of various sizes, some not exceeding a quarter of a line in diameter, others being at least two inches; sometimes a number are found together, either attached to corals, shells, or other hard bodies, or, as most frequently, to the rock itself. This junction of the pedicles, in many specimens, produces the appearance of a number of columns emanating from one common root, but by making a section they are all found to be separate animals, as the columns may then be perceived to be perfectly distinct from each other, passing through the mass, each surrounded by a cone formed of concentric laminae, which cones, by the exudation before mentioned, have, outwardly, become so intermingled with each other, as to form apparently but one mass.

The longest animal of this kind met with by this gentleman, he describes as composed of 158 joints, forming a column about ten inches in length, the circumference of which diminishes slightly above the pedicle, but continues of the same size (viz. about an inch) until it arrives at the upper part, where it expands to the extent of four or five inches. The seat of the greatest motion appears to have been about the centre of the column, which is shown by its increased strength of articulation in that part, exhibited in the radiating grooves being very deeply marked, whereas in the upper and other parts, where but little motion was required, these indentations are exceedingly minute. This column is composed of rings which are thicker at the circumference than at the centre, each being perforated in that part with a round hole, and thus the lenticular cavities formed by the juxtaposition of the plates are connected together.

The head consists of the enlarged columns, to which are attached five wedge-shaped joints, five inferior and five superior costal joints, and five bones called scapulae, to which are articulated ten arms, which are furnished at their sides with a number of feelers, forming a sort of fringe. The upper or columnar joint has five radiating elevated ridges upon its upper surface, between which are the attachments of the five wedge-shaped joints, which are triangular and flattened at the lateral edges, being the points where they are articulated with each other, having two equal articular surfaces at their upper surfaces, divided by an elevated ridge, above which the five inferior costal joints are placed, which are also of a triangular shape, and are connected with each other by lateral attachments, and present a cavity above, which receives the superior costal joints, which in like manner receive the scapulae. It appears probable that an intervening muscular organisation existed between the articulating faces of the joints, from the wedge-shaped ones upwards to the scapulae. There is also a gradual approximation of their internal and external edges, and this, joined to their circular arrangement, produces a conical cavity with the apex downwards. Mr. Pearce suggests that this was probably closed above, as that of the pentacrinite, with an integument composed of a membrane covered externally with scales

of an angular form, forming the cavity of the stomach; between the wedge-shaped joints five canals are also found passing from the lower part of the stomach, each of which terminates in an opening on the external surface, the mouth of which is marked either by a depression or an elongation which sometimes extends to the distance of an eighth of an inch, which openings he supposes to have been the mouths of the oviducts. To the superior surfaces of the five scapulae are attached the ten arms, which appear to have consisted of at least forty or fifty joints, shaped like a horse-shoe, which are articulated to each other, and gradually diminish in size; as they approach their upper extremities a small perforation penetrates each joint, as before described in the vertebral column, through which foramina it is possible the vessels for their nutriment, or the ligaments by which they were attached to each other, had their passage. The arms have also a groove running the whole length of their inner surface, while the outward one is of a rounded form, and to the holes of each joint of the arm is attached a finger whose joints are at first round, but afterwards grooved at their external edges, and which are also perforated. Each arm, when perfect must, according to this description, have had from forty to fifty fingers attached to its sides, placed alternately, and thus presenting a fringed appearance.

He names his first species *Apiocrinites globosus* from its having the head in a very globose form. It is shorter than the other two species, and the irregularities on the surfaces of the joints, which were probably produced by muscular contractions, are very faintly marked.

The *intermedius* has the head elongated, with no corresponding lessening in the circumference, or thickening of the joints, which are thin and deeply crenated, and the muscular impressions, as in the *globosus*, but faintly shown.

The *Elongatus* is distinguished by the head being very greatly elongated in many specimens, tapering down nearly to the centre of the column; the plates are also at least three times thicker than those of the other two species. The column is also of much greater length, without any corresponding diminution of circumference. The development of the various articular surfaces is also very strongly marked, and the plates have a tendency to become more acute at their edges, than in the other species. The radii on the surfaces of the plates of the column are so slightly marked as to be scarcely visible, and on each of the surfaces of the joint a central depression is found, which is occasioned by the joint becoming at once two-thirds thinner at that place than the surrounding portion. This is also seen slightly in the two other species.

Such is a summary of the account given by Mr. Channing Pearce, the whole of which deserves the particular attention of all those who make organic remains their study.

The geological distribution of the *Crinoidea* is also highly interesting. They occur in all the formations, commencing with the transition limestone, in which impressions and portions of these animals have been found. Their great depot, however, is in the mountain limestone, in which no fewer than twenty of those described by Miller are found, together with many of the new genera and species not known to him. They are also abundant in the lias, in which, however, several of the species found in the lower formations disappear, and others of hitherto unknown genera occur.

Some, as the *Apiocrinites rotundus*, are found in the oolitic formation alone, while *Apiocrinites ellipticus* occurs only in the chalk, and another, supposed to be the *Pentacrinites caput Medusæ*, appears to have continued from the deposition of the lias until the present time, forming one of those links between a former state of existence and the present appearance of animated nature, of which so few are to be found even after the most patient and laborious research.

**CRINUM** (Linnæus). A genus of magnificent bulbous stemmed plants, natives of warm latitudes in all quarters of the world. Linnæan class and order, *Hexandria Monogynia*; and natural order, *Amarylloideæ*. Generic character: spathe including many flowers; germen either sitting or on a short pedicel; perianthium tubular at the base; limb regular, spreading, six-cleft; segments alternately furnished with a nail at the point; stamens inserted into the tube, erect; filaments awl-shaped; anthers incumbent. This is one of the most stately of its order; the roots, stem, leaves, and flowers of most of the genus are all ample, and consequently require large pots, a rich loam, and much head-room to grow in perfection. They flower frequently in the stove, and are propagated by offsets which they occasionally produce. But if suckers are not produced naturally, the plants may be easily made to send them forth plentifully, that is, by cutting down the stem to prevent flowering. The *C. amabile* is one of the largest and most valued of the genus, and not so much for its frequent flowering, as for its rich and powerful fragrance.

**CRIOCIDERIDÆ** (Leach). A family of coleopterous insects belonging to the section *Tetramera*, and forming the subsection *Eupoda* (Latreille), having the body of an elongate form, with the head and thorax narrower than the abdomen; the antennæ filiform, or thickened towards the tips, inserted in front of the eyes, which in some are entire and round, whilst in others they are slightly notched in the inside; the head is deeply inserted into the thorax, which is cylindrical or transversely square; the abdomen is large, compared with the rest of the body. The tarsal joints, with the exception of the last, are furnished beneath with cushions, the penultimate (or rather the antepenultimate) being bifid or bilobed; the hind legs are greatly dilated in some of the species, whence the term of the subsection is derived. These insects are essentially herbivorous in their larva and imago states; many prefer the lily tribe, upon the leaves of which the larvæ feed. Those of the *Donacææ* feed within the stems of various aquatic plants upon which the perfect insect is found very abundantly. The species are for the most part of small size, but elegantly ornamented with various colours. Latreille divides the family into two tribes.

First, the *Sagrides*, having the mandibles terminating in an acute and entire point, and the lower lip deeply cleft; the hind legs are generally very large. Here belong the Brazilian genus *Megalopus* and the Chinese and African genus *Sagra*, together with *Orsodachna*.

Second, the *Criocerides*, having the mandibles truncate at the tip, with two or three strong teeth, and the lower lip entire. *Donacia* (which see). *Macrolepta* (*Hæmonia*, Meig.), *Crioceris*, *Zeugophora* (*Auchenia*, Latreille), all of which are British, and *Petauristes* and *Megascelis*, exotic genera.

The genus *Crioceris* is distinguished by having the antennæ short, the maxillary palpi filiform, and the

hind legs not differently formed from the anterior. The eyes are notched, the hind part of the head is narrowed into a kind of neck. The insects of this genus live upon liliaceous plants, asparagus, &c., and make a slight noise when handled; their larvæ also feed on the same plants, to which they hold tightly with the assistance of their six short legs. The body of these larvæ is short, thick and fleshy; and in order to guard themselves from the attacks of their enemies and the changes of the weather, they form a covering of their own excrement, similar to that constructed by the larvæ of the *Cassidæ* (which see). When they have acquired their full size they descend to the earth to undergo their transformation.

Reaumur has given the most complete account of the proceedings of these insects. The figures referred to by Mr. Curtis do not represent a merdigerous species as described by him. There are seven British species, including the type *Chrysomela merdigeræ* (Linneus), which is found upon the white lily. The larva of the pretty asparagus beetle, *C. asparagi* does not form an excrementitious tent\*.

**CRISTARIA** (Schumacker). This genus of shells was constituted by Schumacker, but has since been united with the genus *Anodon*, of which it must only be considered a division. The shell is oval, rounded, gaping at the ends, with something resembling a crest at the summits, and a long longitudinal callosity, divided into two plates by a linear cardinal indentation.

**CRITHMUM** (Linneus) is the generic name of the British maritime plant samphire, found on rocky shores, and cultivated in some places and disposed of for pickling. It affects a very light sandy soil, and belongs to the natural order *Umbelliferae*.

**CROCODILE**—*Crocodylus*. A genus of saurian reptiles, forming, along with the alligator and the gavia, a well marked and very distinct family, the largest, most powerful, and the only ones which are in any way dangerous to the human race. Some account of the more remarkable species of alligator will be found under that title, in its order in the alphabet, so that we shall have here only to notice the two remaining genera, the account of which we shall be enabled to shorten, by bringing them both into one article.

The characters of the whole family are: size very large; tail flattened on the sides; fore feet with five toes, hind with four, of which the outer one is without any claw; all the feet are more or less webbed; a single row of teeth in each jaw; the tongue fleshy, flat, and so much attached to the sides of the under jaw, that the ancients supposed it to be wanting; the back and tail covered with large and strong scales of a square form, ridged at the middle; and a crenated scaly crest along the tail, forming a double row at the basal part; the scales on the under part are square, but small, smooth, and without any keel.

The mouth of these reptiles is a very formidable instrument, although it does not answer all the descriptions that have been given of it. The lower jaw extends farther back than the upper, so that there is room for the insertion of very powerful muscles, both for opening and for closing this jaw, the motions of which are as extensive as they are powerful. It is not true, however, that these animals have a motion in both jaws, as was believed by the ancients, and is

\* At the present time (middle of June) the asparagus, which has been left uncultivated in our garden, is swarming with this insect, not only in its perfect state, but also in that of the larva.

still asserted in some of the works on natural history ; and it is easy to see that such a motion would do them harm rather than good.

There are some of the serpents which can not only turn both jaws till they are in the same plane, but distend the opening considerably beyond the mere measure of the two jaws, when they have occasion to swallow large prey. But the mouths of these serpents do not form an analogy for the mouths of the crocodile family. In serpents, the mouth is generally only a swallowing apparatus, and those which capture large prey are either poisoning serpents, which kill by the fangs, or crushing serpents, which kill by the folds. The crocodiles, on the other hand, are biting animals, which kill with the mouth ; and such animals would have little or no power if they had a motion in both jaws. The action of muscle against muscle in an animal, would be the least profitable way in which it could exert its strength, as the effect would be only equal to the difference of the exertions after the stronger muscle had forced the weaker one to a state of rest ; and thus, the animal would lose an effort equal to double that made by the weaker muscle. There are no such mechanical bungles as this in nature ; and it is a good rule in judging of the truth of what is alleged of any animal, to consider whether that which is alleged is consistent with the utmost perfection of mechanical skill—the producing of the greatest effect by the least exertion ; and if this is not the case, we may rest assured that that which is alleged is not true.

The nostrils of the crocodile are formed externally of two slits which cross each other, the angular pieces between serving as little valves to close the aperture when necessary ; they lead by a long canal through the palatal and sphenoid bones to an opening in the back part of the mouth ; the ear closes externally by means of two fleshy lips, which close it like valves ; the eyes have a third eye-lid ; and there are under the throat two small holes, which lead to glands secreting an unctuous matter which smells very strongly of musk. So abundant is the quantity of this matter, and so powerful its scent, that in warm countries, where crocodiles are abundant, they perfume the whole country around the rivers.

The vertebrae in the neck of the crocodiles are furnished with a sort of false ribs on the sides, which hinder flexure in that direction, and thus the animal cannot turn its head very readily aside, or even turn its body (for animals which have the neck stiff always have difficulty in turning laterally). But the crocodile can turn the neck very readily, so as to elevate the head till the line of it forms less than a right angle with that of the body ; and it can also move the head very rapidly from this elevated position to one rather lower than the horizontal line.

These motions of the neck answer better with the habits of the animal than if they had been in the other direction ; for the crocodiles do not pursue their food either along the banks of the rivers or in the water. They are liars in wait, as is the case with all large and heavy animals of predatory disposition, unless it be those species which have the wide sea for their field of chase. The crocodile is a powerful animal even upon land, but its chief scene of action is in the water, where it watches by the places to which land animals come to drink, with only the point of the nose above the surface ; and as, at these times, it is perfectly still, other creatures approach near it with-

out being aware of their danger. When the animal comes sufficiently near, the mouth of the crocodile opens rapidly to a great extent by the bending backwards of the head and upper jaw upon the joints of the neck as a centre of motion, and the moving of the under jaw in the other direction upon its own articulation. Thus, in the opening of the mouth, there is a motion of both jaws from each other ; and when they are again closed, the upper jaw does descend to meet the lower one ; but the motion of the upper is not against that of the lower, as they are not articulated on the same centre or the same bone. Hence the peculiar motion increases the force of the bite instead of diminishing it ; as the bite is given with both jaws, which, when they come to a state of rest, the upper offers a point of solid resistance to the under.

CROCODILES, properly so called (*Crocodilus*). The name "crocodile" is Greek, and means that which cries, yelps, or screams, along the bank of the river. The true crocodiles are the most powerful and ferocious of the race. The characters in which they differ from the gavials are: the muzzle oblong and depressed, the teeth of unequal length, but the four front ones below do not fit into holes in the upper jaw, as in the alligators. There are several species or varieties ; and there are in the West Indies, in the rivers of the larger islands, some which have the muzzle of the crocodile form.

CROCODILE OF THE NILE (*Crocodilus Niloticus*). This is the animal which is meant whenever the crocodile is mentioned without any farther explanation. It has long been known, and there are few animals of which so many stories have been told. There is not much use in repeating any of those stories, though we must not judge of the animal altogether from what is observed of it in Lower Egypt, which is the most northerly latitude in which it is found, and therefore it must have less energy than those in the south. With the exception of the elephant, the rhinoceros, and the hippopotamus, the bulk of the crocodile perhaps exceeds that of every terrestrial animal ; no fishes frequenting fresh water equal it, and but a few species of those belonging to the seas. The largest are not less than thirty feet in length, and one of only half that size is five feet in circumference ; the body stands low on the ground, and the animal universally presents a dull and sluggish aspect. Nevertheless, its motions in pursuit of prey are not slow ; and the difficulty which it finds in turning is the surest means of escape on land ; its agility in water is infinitely greater.

These facts are better illustrated when the animal is roused to action. Its natural abode is in the water, for scarcely one fourth of its existence is passed on the earth ; whence those narratives which affirm that it lives entire months without that element, are not easily to be credited. The muddy edges and thick reeds of slow and tranquil streams are its favourite haunts ; and it sometimes descends rivers to within the flowing of the tide. On leaving them it advances always with a slow pace, nearly in a straight line, its belly frequently dragging on the ground, and its head commonly elevated before it. However, it is seldom seen standing, and its chief enjoyment seems to be lying in a state of absolute quiescence. When in pursuit of prey, it swims gently and silently, just on a level with the water, until it approaches the place where some terrestrial animal comes to quench its thirst. Then curving its tail, it strikes the animal a

violent blow, which is invariably in the direction of the water, and at the same time towards its own mouth. Should the animal surprised be of large size, such as an ox or a horse, the crocodile adopts another manoeuvre, in seizing it by the nostrils, and forcibly dragging it under the water to be drowned. When a tortoise is seized, the crocodile raises its head above water, and with the inconceivable strength of its jaws, crushes the shell in pieces. Men, and particularly negroes, are said to be its favourite prey, and it is greedy after the flesh of dogs; and hence, the negroes that hunt the crocodile are accustomed to beat the dogs on purpose that their howling may attract it from its haunts. The prey being drowned, is conveyed to some sub-aquatic hole or receptacle, and left to putrefy before it is devoured; but the crocodile cannot feed in the water; it would then, as is usually credited, experience the same fate as its victim; therefore, except small fishes, the prey is always carried to the land. Its structure also is such, that it must rise to the surface once in an hour, or hour and a half, for breathing. Nothing that it once seizes can escape; it never quits its hold; even strong levers forced between the jaws for that purpose have proved ineffectual; and, shaking its prey to pieces, it is swallowed without mastication. Much has been said of the stratagems employed by the crocodile to seize its prey; that it lies like a log on the banks of rivers, or floats inactive on the surface, and then springs forward whenever the victim comes within its reach. This may be partly true, though it appears under many exaggerations; for it is well authenticated, that it remains motionless until considerable objects are quite close and evidently within its reach, then it leaps upon them. The agility of the crocodile is not so great, even when in pursuit of prey, that a man may not escape at tolerable speed, more especially by frequent deviation from the straight path. The blow with the tail, suddenly given, is principally to be dreaded, and the irascibility of the animal when attacked, or the female at the head of her young.

It does not appear that the crocodiles are so numerous in the lower part of the Nile as they were in ancient times, and the few that do appear are now not much dreaded there—but farther up the river where the climate is warmer. But Lord Prudhoe, while travelling in Sennaar, between the black and white Nile, in the averaged latitude of about 14° north, found that they were much more formidable; and during his sojourning in the country several of the natives were carried off by them; and the banks of the river were in many places so musky in their smell as to be very offensive.

Crocodiles are oviparous, and the eggs are but small in proportion to their size, not being quite so large as those of a goose. They are, as is the case with the eggs of reptiles generally, equally thick at both ends, they are covered with an envelope which hardens in the air, but it contains very little carbonate of lime. The males are more numerous than the females, and fierce battles ensue between them in the pairing time. These battles of gallantry are generally decided in the water, and they are accompanied by the most dismal bellowing that can possibly be imagined; this noise is said to resemble that both of the bull and the bittern, but to be much louder and more husky and dismal than either.

The female digs a cavity in the earth, in which she places her eggs, in a circular form, in successive layers,

and with portions of earth between, the whole being afterwards covered up.

This nest is generally placed in a dry hillock, and the earth is gathered up, so that on the average, the eggs are about ten inches below the surface. This being done, the mother abandons them to be hatched by the heat of the sun; yet instinct prompts her frequently to revisit the spot, as the term of exclusion approaches. She then testifies uncommon agitation, roaming about the place and uttering a peculiar growling, as if to awaken her hideous offspring to animation. The period of maturity being at length attained, the nascent crocodiles answer to her solicitude by a kind of yelping like puppies. A hollow murmur in return denotes her satisfaction, and she hastens to scrape up the earth with such anxiety, that several of the young are generally crushed under her unwieldy body. Having withdrawn them from their nest, the mother leads them straightway to the neighbouring water; but now her utmost vigilance is required for their preservation, for, unlike the instinct with which she is animated, the male, silently approaching, will frequently devour them before she is aware of her loss. He perpetually seeks their destruction; and the watch of the female over her young is protracted for three months from their first appearance. An opinion is prevalent that the crocodile continues growing during its whole existence, that it lives to a great age, and that the utmost limits of its size are scarcely known; whence, in addition to well authenticated instances of some being twenty-five or thirty feet in length, others are reputed to attain the enormous dimensions of fifty feet. Though we are not enabled, from positive and conclusive evidence, either to corroborate or to controvert these facts, the observations of the naturalist already cited, throw considerable light upon the subject. Where animals live in a state of uninterrupted warfare, we are aware that there is little probability of their either attaining their extreme dimensions, or the utmost duration of life; and with respect to the latter, we are inclined to ascribe a much longer period to those that dwell in the waters than is usually allowed. The crocodile of the Nile, banished to the most southern parts of Egypt, is permitted to live undisturbed, and there it is universally admitted to increase to the largest size, far exceeding what is seen in other countries.

Were not the fecundity of the more powerful and destructive animals repressed, either by the attack of open enemies, or their own liability to perish, they would speedily overrun the earth. It is thus that almost all are confined within moderate bounds; that destruction is ever commensurate with multiplication, and sometimes by its preponderance entire species become extinct. Many animals have inhabited this island, of which there have only been fossil remains for ages; and an authentic record has preserved the period when the last of a noxious race was destroyed. In certain places, once infested by the crocodile, it is now totally extirpated, and in others its appearance is rare. In its earliest stage we have seen that it is liable to perish, either from being crushed to death by the female or devoured by the male. A species of tortoise frequenting the Nile, makes incredible havoc among the young. The hostility of the ichneumon has been related from times of remote antiquity; and though we cannot agree that it proves destructive of the crocodile itself, we at least know that it devours the eggs. In this manner, the numbers of so formi-

dable a creature, when less capable of defence, are diminished; but after having attained its utmost power, different means repress its voracity, and other enemies are on the watch for its destruction. Although the crocodile drags its prey under water to extinguish life, we have already remarked, that it must resort to shallows or the land to feed upon it; and in like manner, when attacked by the sword-fish or shark, it is easily vanquished, for on opening its mouth in resistance, a torrent of water rushes in, and it is drowned. Of all the enemies, however, which the crocodile has to dread, the most inveterate is man. By a perpetual and sanguinary war carried on against it in almost every country, and by the various devices adopted for its capture, the race is prodigiously reduced. But it is no easy matter to overcome an animal endowed with such uncommon strength, and whose hide in general is impenetrable by a leaden musket ball. It is, however, more vulnerable in the belly, and a bullet discharged down the throat or into the eyes is fatal. Even harpoons or spears will penetrate the body and inflict mortal wounds, if thrown by a skilful hand.

As the habits of the different species of true crocodiles do not vary much, except in so far as depends upon difference of size and strength, and difference of activity, which is always greater the warmer the climate, a mere enumeration of the remaining ones will be sufficient.

**ST. DOMINGO CROCODILE** (*Crocodilus acutus*). The muzzle of this species is longer in proportion than that of the former, more pointed at the extremity, but enlarged at the base. The scaly plates on the back are ranged in four lines, the lateral ones anterior and with very elevated crests. This species is exceedingly common in all the rivers and marshes of St. Domingo, and most of the other large West Indian islands. It has been confounded with the crocodile of the Nile, also with the caimans of the American continent, and its manners correspond exactly, though there are some differences in its external structure.

**TWO-CRESTED CROCODILE** (*Crocodilus bifurcatus*). This is the crocodile of the east, and is more abundant in the islands than on the main land of Asia. It has been seen as far to the southward as Timor, but it does not appear to have been hitherto found in Australia. It is reported, however, as being more discursive in the water than any of the other species, so that it has been met with a good way out at sea. It is browner than the Egyptian crocodile, and the dark spots upon it are more distinct.

Crocodiles have been observed in all the great rivers of Africa, and in the streams and marshes of the oriental islands, and also in the larger rivers of the extreme south of Asia, differing considerably from those now mentioned, although only in a few unimportant particulars. But the manners of the whole race, wherever they may occur, or however they may differ from each other in a few external particulars, are so much the same that, for popular purposes, any further account of them is unnecessary.

**GAVALS.** The distinguishing characters of the gavials, at least in point of shape, are these: the muzzle slender and very much elongated; the teeth of nearly equal length, the fourth in the lower jaw passing into notches and not holes in the upper jaw; the hind feet are dentated on their external edges, and the webs reach to the roots of the claws; two large holes are perforated in the cranial bone in the rear of the eyes,

which are perceptible through the skin. The most remarkable physiological character consists in these animals being much more aquatic than either the true crocodiles or the alligators. They repose on the mud in the shallows; but their food consists almost entirely of fishes, aquatic reptiles, and other living productions of the waters, seldom meddling with any warm-blooded creatures and never with man. There are only two known species, both of which are inhabitants of the south-eastern parts of the old continent.

**GAVAL OF THE GANGES** (*Longirostra Gangetica*). This species appears to have been known to the ancients, who describe the Ganges as containing two sorts of crocodiles, one harmless and the other not. This species is of course the harmless one. The other species is the little gaval (*L. tenuirostra*), which is hardly known except as a museum specimen.

**CROCUS** (Linnæus). One of our commonest, earliest, and most favourite garden flowers. It belongs to the third class of the sexual system, and to the natural order *Iridææ*. The crocus is found wild in different parts of Europe, three of them in Britain, one of which is the cultivated saffron. The garden varieties are numerous, and all are very attractive. No flower is so sensible of the effects of light and heat as the crocus. Its petals expand during the day, and close at night. But they will expand at night under the light of a lamp or candle; or if placed within the influence of the heat of a fire, though shaded from the light of it, the petals open as readily as they do in bright light. The crocuses are mostly summer sleeping plants, particularly the spring flowering species; and when the spring growth ceases, the tubers are usually taken up and kept in a dry place till the early spring, when they are again planted where they are intended to flower.

**CROSSANDRA** (Salisbury). A splendid flowering evergreen shrub, found in India. Linnæan class and order *Didymia Angiospermia*, and natural order *Acanthaceæ*. Generic character: calyx of five unequal parts, supported by three bractes; corolla salver-shaped, of one lip, which is large, flat, and five-lobed; stamens within the tube; anthers one-celled; capsule two-celled, two-valved; seeds netted. This genus is called *Harrachia*, by Jacquin, and *Ruellia*, by Andrews. The stove management of these plants is easy; they flower frequently, thrive in light rich soil, and are propagated by cuttings.

**CROTALARIA** (Linnæus). So called because the seeds of the genus rattle in the pods like *Krotalons*, or castanets. Many of the species are annuals and natives of warm climates. Linnæan class and order *Monadelphia Decandria*, and natural order *Leguminosæ*. Generic character: calyx two-lipped, five parted; vexillum or standard large, and reflexed; keel pointed; tube bearing the stamens; style downy; pod on a pedicel, oblong. The shrubby species of this genus have been long cultivated in our hothouses; they flower freely, and sometimes ripen seeds; but in default of these, cuttings may be rooted in sand under a glass in hotbed heat.

**CROTALUS**—Rattle-snake. A genus of ophidian reptiles, belonging to the poisonous division of the true serpents, and to that subdivision of them which have poison-fangs, unaccompanied by any other teeth. They are the typical serpents of this subdivision, and form a tribe, consisting of *Crotalus* properly so called, which have a rattle, or instrument of sound upon the tail; and *Trigonacephalus*, tri-

angular-headed serpents, which have not, but are fully as formidable as the others. With the viper family, which consists of more genera than this one, all poisonous, but of smaller size generally than the *Crotali*, and diffused over a greater variety of countries, these serpents make up the whole of the division.

It will be proper, therefore, to preface our brief notice of some of the more remarkable species of these formidable reptiles by a very brief sketch of the peculiarities which distinguish them from all the other serpents.

Their upper maxillary bones are very small, without any teeth, but having upon a long peduncle on each side, which answers to the external pterygoid process of the sphenoid bone, a very sharp tooth, which is perforated longitudinally by a canal, through which the deadly virus of the animal is injected into the wound made by the tooth. These two teeth are the poison-fangs of the animal; they are very sharp at the points, rather slender in proportion to their length, and awl-shaped, or adapted for inflicting punctured wounds only, and not for tearing or lacerating, so that the wounds which they inflict are not calculated to do much mechanical injury to their victims. Indeed, this addition would be quite superfluous, as the poison is of itself sufficient to kill almost any native animal of the places where these serpents are found; and it is a law of nature never to waste any power in the creatures which she produces, whatever may be the functions which they are called upon to perform. When the reptile is in a state of repose, these two deadly weapons are folded down into grooves in the gums; but when it is excited, they are erected, and their points so borne, that they are the first part of the reptile which strikes its prey. It is not the tooth which moves upon its peduncle; it is the maxillary bone which moves, and brings the fang into a proper position for wounding, at the same time that it has firmness enough for inflicting the wound. The virus is secreted by a gland of considerable size, situated on each side of the head, immediately under the eye; and the same muscular action which forces the tooth into the body of the prey compresses the reservoir of venom, and so forces it through the canal of the fang into the wound.

All venomous serpents are ovoviviparous, that is, the eggs are hatched internally, and the young brought forth alive; so that, whenever the eggs of a snake are met with in the ground, it may always be known that the snake is a harmless one. It is on this account that they have been called "vipers," which is a contraction of *vivipara*.

As the deadly virus with which these reptiles are armed, dreaded as it is, and fatal as it has proved in many cases, is nevertheless given to them for their own good, and not for the injury of other animals, excepting in so far as these serve as food to the reptiles, we might naturally suppose that both the *crotali* and the *vipers* must feed upon large game, that is to say, upon game which they would not be able to manage without these formidable weapons. Accordingly, we find that the mouths and gullets of all of them are capable of great extension.

The heads of these serpents are large backwards, so that there may be room for the apparatus which works their deadly fangs, and admit of the dilatation of their great gape. Their eyes are also fiery, and

they are altogether irascible in their aspect, and seem to partake all over of some of the deadly virus with which they are armed, and by the help of which they procure their food.

But we must not blame them for all this. Their peculiar structure, and the places in which they seek their food, do not enable them to strike it down like the birds of prey, nor to course it, or spring on it, like the predatory mammalia. We have also an example of the same sort of conduct in man, and we have it most remarkable in the very parts of the world where such creatures are most abundant. The poison with which the natives of the interior of Guiana, of southern Africa, of some of the Asiatic isles, and other places, prepare their darts and arrows, is almost literally man playing the *crotalus*, in that feebleness of his proper powers, or rather of the proper cultivation of them, which makes the savage stand to the civilised man in nearly the relation in which the serpent stands to the lion and the eagle. It must be admitted that civilised man, with his powder and shot, is not much better than the *crotalus* with its poison; and then there is this weight in the scale against him, that he discharges his stroke against his own species, and when the action is not to produce him a meal, which the reptile never does.

These poisonous serpents are not supplied with either the activity or the strength of the species which are not poisonous. Their movements are slow, and their dispositions tranquil, and they never appear to use their weapons unless when compelled thereto either by necessity or by fear. They are all inhabitants of the American continent; and some of them, though the winter is much colder than in the same parallel of Europe or Asia, are found much farther to the north than any serpent of nearly the same deadly venom is met with in the eastern continent. Those which are found far to the north (and, though they are not abundant, they are not altogether unknown in Canada) are abroad and dangerous only for part of the year, and remain in their holes in a torpid state while the severity of winter lasts; but in the tropical parts of the country they are never torpid, though they remain in hiding places, or are, at any rate, inactive during the rains.

The very high temperature of the summer months, even in those places of North America which are cold in the winter, and also the abundance of food, and of undisturbed caves for their residence, are no doubt the reasons why they are found in such northerly localities in that part of the world.

In the true *crotali* which have the rattle, or sounding apparatus, on the tail, there are considerable varieties, so that no specific character can be founded on the number of pieces of which this instrument consists. The pieces or bells consist of truncated pyramids and hollow collars, both of the nature of scales; and when the animal puts its tail in motion, these rattle against each other. As these do not contain any living part of the animal, but are mere appendages to the tail, the last ones are apt to drop off, just as is the case with the spine or claw which is sometimes found adhering to the skin of the lion's tail in the centre of the terminal brush. It does not appear that this rattle is of any use in the economy of the animal, or, which comes very much to the same thing, the use of it is not known. It cannot, as has sometimes been alleged, be of much use in warning other animals of the appearance or

presence of the serpent, and thus enabling them to make their escape, for the serpent must be one of very large size, and also very much excited, in order to be heard at the distance of four or five yards; and on the ordinary slow march of the animal it makes very little noise.

The smell of these serpents is exceedingly offensive, even when they are alive, arising, as is supposed, from the rapidity with which the flesh of those animals on which they feed putrefies from the action of the virus upon it. This virus is not a poison when taken into the stomach of other animals, and there is no reason to suppose that it is such when taken into the digestive organs of the reptiles themselves, while the effect to the bitten animal is a general putrefaction of the body, and we must suppose that this extends to the reptile also; and we have proof that it does, for the dead bodies of all the poisonous serpents putrefy very rapidly, and are exceedingly offensive to the smell during the process. Serpents which are not absolutely poisonous, but which swallow their prey entire, and in large quantities at a time, as is the case with the boas, pythons, and other great crushing serpents, have the same kind of smell, though it is not perhaps quite so offensive as that of the crotali.

Hence it should seem that there is a power of the decomposition of animal matter about all the true serpents, whether it is concentrated into a direct and local poisoning apparatus or not; and this great power of decomposition appears to be necessary for the animals, as they have not the means of separating the digestible parts of their food from the indigestible before it is taken into the stomach; neither do they appear to return any of the indigestible parts in castings, as is done by owls, and various other birds.

The crotali, and the other members of the subdivision, require the stimulus of the warmest climates and seasons to call forth their energies, and even the common state of the hottest countries does not, upon ordinary occasions, seem capable of rousing them to their full powers. It has been matter of observation, that they have more than common activity; and are more dangerous than ordinary, when the air is in a highly electric state.

This is less or more the case with all animals, and even with the human race, protected as they are from at least some of the vicissitudes of nature by artificial means; and it is very worthy of remark, that those serpents are the animals which are at once most strongly excited by the physiological circumstances of their own nature during the times they are in action, the most dependent upon high temperature for their activity, and the most energetic when most exposed to an electric state of the atmosphere. We have here the facts brought together in the instance of the very same creature, that the energy of life, the intensity of heat, and the excitement of electricity, increase and decrease together; and, if this is not proof that the three principles are one and the same, only differently modified, by being exerted through different combinations of matter, it proves to a demonstration that they are very closely related.

Serpents of this subdivision do not climb trees, neither do they move about with the flexible graces and waving motions of the harmless serpents. When they are on the march, they proceed in a straight course; and when they lie in wait for their prey, they all assume that position which is so well known under the name of the "adder's coil." Every one

who has seen a lurking adder, must be aware that the centre of this coil, or spiral, contains the head of the serpent; that the head is elevated to some length, in order to give the animal a view of whatever is around it, but that the greater part of the body is coiled level on the ground, and that it is the uncoiling of this spiral, acting very nearly in the same manner as the unbending of the spring of a watch, which gives them their impetus. If the enemy, or rather the prey, is of large size, they are worked into a corresponding degree of irritation; their eyes gleam—their cheeks are inflated—their lips are pulled tight—their large gape is opened to the full extent—their fangs are erected, ready to inflict the fatal bite, and their lengthened tongue is lolled out, as if in mockery of any defence which may be offered against that terrible poison with which they are armed.

But though upon the appearance of large prey, and especially of danger, they are excited apparently to madness, and their whole body quivers as if they themselves were under the influence of some terrible stimulus from without, yet there is method in their madness, and they will not spring upon any animal which they are unable to swallow, unless they are reduced to extremities by impending hostility; so that it will be found that the greater number of those who are bitten by these serpents, are either bitten in consequence of treading unawares upon them, or for making an unskilful attack. The most poisonous of them, if it sees a man or other large animal, when on its ordinary march, will get out of the way as fast as possible, and conceal itself in the nearest cover; but if it is coiled, and waiting for prey, and especially if its prey is in sight, it cannot be expected to quit its position without showing resentment; for there are few domestic animals which, when hungry, suffer themselves tamely to be driven from their food.

Birds which feed on the ground, various reptiles, squirrels, rats, and, generally speaking, all mammalia not larger than hares (according to the size of the individual serpent), form the common prey of the crotali. As they are no climbers, and as their motions on the ground are so slow and so much in the straight line that they would have little chance of capturing any prey by pursuing it, they necessarily have recourse to springing from the coil; and, in so far as animals of different classes can be compared, they bear no inconsiderable resemblance to the cat family, only these spring from the crouch, while the poisonous serpents spring from the coil. But it is worthy of remark, that the more powerful cats which spring upon large prey, invariably work themselves into a state of great excitement before they throw themselves upon their prey; and it is not less worthy of remark, that the cat family are remarkable for the excitability of electric action in them; and it is probable that it is an instinctive effort to lessen the annoyance of atmospheric electricity, which induces the common cat to wet its fur, or wash its face as it is usually expressed, in electric states of the air.

The power of fascination which these serpents have over their smaller prey, has been so often mentioned, as to leave little doubt that it is in a great measure true; and they are not the only animals which, upon sight of their mortal enemies, are rendered quite helpless by excess of fear. That they themselves can be charmed by musical sounds seems also to be established upon pretty good authority; and for this also there are precedents among the other animals; indeed

there is perhaps no animal but which may be turned from its momentary instinctive impulse, and brought to simple attention by one combination of sounds or another; and it will readily be understood that if once this is done, the former impulse of the animal is gone for ever, and cannot return without a return of those circumstances which, according to the general nature of the animal, give rise to that particular impulse.

This is a most important point in animal physiology, and one which ought never to be lost sight of; and it explains many circumstances connected with the conduct and apparent characters of animals which otherwise would be perfectly anomalous. Upon this principle very many of those marvellous stories which are told of animals leaving their natural instincts, and sparing that which it is constitutional for them to devour, which have often been attempted to be explained by something approaching to human sagacity, to grateful memory, or to both in the animals, can be much better explained as arising from the fact of the animal having no speculative sagacity and no suggestive memory at all, but as being mere creatures of the moment, incapable of drawing inferences from the past, and of forming plans for the future. The fascination of their prey by serpents, and the charming of serpents themselves by human art, of both of which, as we have said, there is no reason to doubt, at least to a very considerable extent, evidently arise from the withdrawal of the animal's senses from its object; and keeping them bewildered; and as it requires a much greater effort to work one of those poisonous serpents up to the proper pitch of attacking, than it does most other animals, it is easy to see that if it is once withdrawn from its purpose, it cannot so easily return to it, but must require the same time, and the same train of excitement as before. Perhaps we may have occasion to enlarge a little upon this very curious subject in an article FASCINATION.

From the difficulty, and also the danger of observing these creatures in their native haunts, the genera and species are in a very unsettled state, and it would be foreign to our purpose to attempt an adjustment of them, even though we were in possession of the means; we shall therefore merely mention one or two of the leading ones, remarking that, if the rattle is to be considered as a generic distinction, some other name should be invented for the whole family of the poisonous serpents of America, which are, generally speaking, of much larger size than those of the east, and also more deadly in their virus. In the meantime we may consider them all as *crotali*.

**BUSH MASTER.** This species is perhaps the most for-

Bush-master.

midable in point of size and also in deadliness of bite.

It is found in the humid thickets of the woods of Guiana, and does little harm when left at peace; but it is a very formidable creature when attacked. The preceding figure of it in the act of starting from its coil, will give some general idea of the form and bearing of all the family! This one attains the length of five or six feet; and in those large specimens the poison fangs are nearly an inch and an half in length, very sharp, and thus capable of inflicting a mortal wound in a very large animal, from the depth at which they can discharge the virus.

**COMMON RATTLE SNAKE (*Crotalus horridus*).** This is the more northerly species. It was formerly found six or seven feet long; but it has been so much hunted since the colonisation of North America, that it is not now met with of so large size! It is not dangerous to man or domestic animals, unless attacked, or trod upon accidentally; and the smell of it is so offensive to most animals, as to make them avoid the bushes in which it is lying hid: pigs are the only animals which venture to invade their retreats; for the olfactory nerves of the pig are not only proof against all sorts of smells, but the peculiar nature of his skin and the lard under it is such, that the fangs even of a rattle snake are innocuous to the animal who gobbles up the serpent as a *bonne bouche* wherever he can find it.

The remaining species, with the exception of the small spotted *crotalus*, which is found in the arid plains to the westward of the Mississippi, and so southward into Mexico, and the yellow serpent of the West India Islands, are not so clearly made out as to warrant our giving a popular account of them under their specific names, as these have been framed from museum specimens, with very little knowledge of what the animals are in wild nature, and sometimes in ignorance of the part of the world of which they are natives. Indeed it has sometimes happened that a serpent has been given to very nearly the antipodes of his native locality; thus, as we had occasion to mention in the article COLUMBER, an American serpent has been described in the systems as the Esculapian serpent of the ancient Greeks; and by way of making matters worse, even some of the *crotali* have been represented as coming from Ceylon.

There is much to be learned before the history of reptiles, even in Britain, shall be worthy the name of a science, or rather a scrap of a science, for the reptiles in our islands are so few; and therefore when we consider the vast extent of the localities of tropical serpents, the obscurity of their manners, and the apprehensions that most people have of them, we almost despair of seeing for many centuries anything like even a tolerable system of this singular branch of living nature,—a branch which, from its intimate connection with the most fertile spots, and the greatest energy both of animal and of vegetable life, would doubtless, if rightly understood, furnish one of the best keys to those general operations of nature, which stamp their most prominent characters upon the different regions of the world. For one or two general observations we must refer the reader to the articles OPHIDIA and REPTILE.

**CROTON (Linnaeus).** A tropical genus of shrubs so called, because the seeds resemble ticks. Linnaean class and order *Monœcia Monadelphica*, and natural order *Euphorbiaceæ*. Generic character: male flowers, calyx five-parted; petals five, with glands between each; stamens numerous; filaments free and awl-

shaped; anthers oblong and erect; female flowers, calyx of five parts; petals none; styles three, twice or many-cleft; seed-vessel three-berried. The greater number of these plants are uncultivated; one, the *C. tinctoria*, is cultivated in the south of Europe for the dyer. Those kept in our stoves are admired for their variegated leaves; of which the late Mr. Sweet mentions a curious circumstance, namely, that unless the plants are grown in "a mixture of pure peat earth and sand, the leaves will soon become green, and lose all their variegation."

**CROTOPHAGA**—Ani. A genus of omnivorous zygodactylic birds, natives of the tropical parts of America, of which the characters are: the bill short, thick, arched, and with a trenchant ridge on the culmen compressed laterally, angular at the sides, and without any notch; nostrils lateral, near the base of the bill, oval, and open; feet long and strong, the tarsi a little longer than the outer toe; wings short, the first, second, and third quills gradually increasing, the fourth and fifth the longest in the wing; and the tail long, rounded, and composed of eight large and strong feathers.

From this form of the wings and tail, it might be inferred that these are not birds of long flight, neither do they prey upon the wing. They have some of the structural characters of our magpie, but the feet are formed for more habitual perching. They are, however, much more social birds than the magpies, and have none of the crafty and suspicious manners of these gunning birds. They are social birds, and are always found in small flocks; but they prefer the open plains, and perch on the tops of bushes, or often upon elevated hillocks. They are familiar, and not afraid to perch on the backs of cattle when grazing, in order to pick off the insects with which these are often very much infested in warm countries. Their voice is not very musical, and it has been compared to the sound of steam issuing boiling from a kettle; but, like the sound of the rook, it is better in concert than solo, and it is in concert that it is generally heard, as it is rare to meet with one of the genus single, and as rare to hear one cry without its being instantly joined by another.

Though the companies of these birds which are seen together are not so numerous as those of the rooks, yet they are even more social than these, the most social of all our omnivorous birds. Rooks build in the same tree, but this genus breeds in the very same nest, and old and young may be seen enlarging the nest when the latter are to begin the cares of a family. The nest is substantially made in the large fork of a close bush or tree; the materials are dry twigs, interlaced and lined with fine vegetable fibres. The sides are well raised, and the diameter of the structure is often a foot and a half. The eggs are three or four in number, of a dull greenish colour; and from the community of the nest, it must often happen that the eggs of different mothers are mixed during the incubation. Still that does not disturb the amity of these very social birds. They feed upon maize, rice, and other different sorts of grain, and upon fruits, as well as upon insects and their larvæ, and worms.

There are two species: *C. major*, about the size of a jay, and *C. minor*, about the size of a blackbird. The plumage of both is black, with some reflections of purple and green.

**CROWEA** (Smith). A genus of shrubs from New South Wales, named in honour of J. Crowe,

a celebrated botanist of Norwich. Linnæan class and order *Decandria Monogynia*, and natural order *Rutaceæ*. Generic character: calyx five-cleft; petals five, oval, spreading; stamens inserted under the disk, bearing the germen; filaments flat; anthers two-celled, united to the interior sides of the filaments; style almost none; stigma fleshy and somewhat lobed; disk fleshy, bearing the germen; capsule containing five single seeds. This is a favourite greenhouse plant, as it flowers throughout the greater part of the year. It cannot bear over-watering, and requires plenty of free-air. It is propagated by cuttings.

**CROWFOOT**, is the *Ranunculus acris* of Linnæus, and the butter-cup of the British meadows. It is a very prevalent weed in grass land, in consequence of the flower stem not being relished by cattle, so that the seeds are annually shed where they grow. To extirpate them is a tedious labour, as each individual plant must be rooted out with a forked spud. It is said that if eaten by cows it gives a bitter flavour to butter, but this requires confirmation.

**CRUCIANELLA**. See **CROSSWORT**.

**CRUCIFERÆ**—Cruciferous family. A natural order of dicotyledonous or exogenous plants, containing ninety-eight known genera, and nearly one thousand species. It is a very natural family, and is allied to *Capparideæ*, *Papaveraceæ*, and *Fumariaceæ*, from which orders, however, it is at once distinguished by its tetradynamous stamens. Its essential characters are: sepals four, deciduous, two often gibbous at the base; petals four, in the form of a cross (hence the name cruciferous), alternate with the sepals; stamens six, of which two are shorter, solitary, and opposite to the lateral sepals, while four are larger, in pairs, alternating with them; ovary superior, two-celled; style single; stigmas two, opposite the placente; green glands at the base of the germen and stamens; fruit a siliqua, or silicula, two, rarely one-celled, two-valved, the valves separating from the placente, rarely valveless, one or many seeded; seeds attached in a single row by a funiculus to each side of the placente, generally pendulous, and without albumen; embryo with the radicle folded upon the cotyledons.

The plants belonging to this order are herbs, which are annual, biennial, or perennial, rarely suffruticose. Their leaves are alternate, and their flowers are usually yellow or white, and grow in corymbs or racemes. They grow in greatest abundance in Europe, nearly one hundred and twenty species being found in the northern and middle European countries, and one hundred and eighty on the northern shores and the islands of the Mediterranean. Numerous species are also met with in Asia Minor, Persia, the northern coast of Africa, Siberia, India, New Holland, and North and South America. Besides species whose locality is not well known, or which are common to different countries, we have about one hundred in the southern, and eight hundred in the northern hemisphere. In the temperate zone the number of species amount to six or seven hundred, in the frigid to above two hundred, while within the tropics little more than thirty have been detected. The *Crucifera* are included in the class *Tetradynamia*, the fifteenth of the Linnæan, or artificial system. This class is well characterised by having four long stamens and two short. It is divided into two orders; first, *Siliculosa*, in which the fruit is a roundish pod,

or pouch, as is seen in *Honesty*, *Shepherd's Purse*, &c.; second, *Siliquosa*, in which the fruit is a very long pod, as is seen in *wallflower*, *gilliflower*, &c. Decandolle and others have divided the order into sections, according to the mode in which the cotyledons are plaited or folded, and the position of the radicle in relation to them. The following are the sections founded on these characters:—

I. *Pleurorhizææ*, in which the cotyledons are flat, with the radicle lying upon their edges, as in the genera *Mathiola*, stock; *Cheiranthus*, wall-flower; *Nasturtium*, cress; *Barbarea*, *Arabis*, *Cardamine*; *Lunaria*, honesty; *Alyssum*, rocket; *Draba*, *Cochlearia*, *Thlaspi*, *Iberis*, candytuft, &c.

II. *Notorhizææ*, in which the cotyledons are flat, with the radicle lying on their back, as is seen in the genera *Hesperis*, dame's-violet; *Sisymbrium*, *Erysimum*, *Camelina*, *Seneciera*, *Lepidium*, *Isatis*, &c.

III. *Orthoploceæ*, in which the cotyledons are folded lengthwise, as in *Brassica*, cabbage; *Sinapis*, mustard; *Diplotaxis*, *Vella*; *Crambe*, sea-kale; *Raphanus*, radish, &c.

IV. *Spirolobeæ*, in which the cotyledons are coiled up spirally, as in *Bunias* and *Erucaria*.

V. *Diplocolebeæ*, in which the cotyledons are bent double, as in *Heliophila*, *Subularia*, and *Brachycarpææ*.

This is a most extensive order, including many of our valuable esculent vegetables, such as cabbage, raddish, sea-kale, and cress, and some articles of *matéria medica*, as mustard and scurvy grass. In it too we find some plants used in the arts, such as woad, and others which are cultivated in gardens on account of their beauty, such as stock, gilliflower, wallflower, candytuft, rocket, &c. In general cruciferous plants are antiscorbutic, stimulating, and acrid. The pungent taste and powerful odour which many of them possess are owing to the presence of a volatile oil, which is easily procured by distillation. The properties of the plants vary according to the quantity of this oil which enters into their composition. When by cultivation the plants are made to contain a large quantity of mucilage and water, their acrimony is either altogether destroyed or much diminished, and they become agreeable articles of food. A similar effect is produced by blanching.

Cruciferous plants contain sulphur and nitrogen in their composition, and during the process of decay give out an ammoniacal odour, similar to that evolved from animal substances. In consequence of the nitrogen which they furnish, the plants of this order have been used in place of the horns and hocks of animals in the manufacture of Prussian blue. Their seeds abound in a fixed oil, which is often expressed and put to important uses.

In their botanical, medical, and chemical characters, the cruciferæ exhibit such an analogy and uniformity that it is needless to dwell long on the individual genera and species. We shall notice a few of the most interesting. The genus *Sinapis* furnishes several important species. *Sinapis nigra*, common mustard, is found under hedges and in waste places in many parts of Britain. Its seeds furnish the mustard of our tables. They are very acrid and stimulating, and when reduced to powder and mixed with vinegar and crumb of bread, they form rubefacient cataplasms known by the name of sinapisms. When applied externally these are useful in causing a rapid determination of blood to the surface of the body, and in raising the energy of the circulation. If kept applied

for a considerable time they will even produce inflammation and vesication. The powder or flour of mustard is sometimes administered as an emetic in the dose of a dessert spoonful. It has been given successfully in cases of cholera and gout, and in intoxication threatening apoplexy. The seeds of mustard, according to chemical analysis, yield a fixed and a volatile oil, vegetable albumen, mucilage, sulphur, nitrogen or azote, sulphate and phosphate of lime, and silica. The fixed oil is bland and insipid, and is obtained by expression. The cake which is left contains all the acrimony of the mustard. This acrimony is owing to the presence of the volatile oil, which is procured by distillation. *Sinapis alba*, white mustard, is frequent in waste places in Britain, and is well distinguished by the long beak which terminates its pods. Its seeds are whiter and more mucilaginous, less acrid, and not so large as those of the last species. They were formerly employed to stimulate and strengthen the tone of the stomach. In a young state the plant is eaten under the name of mustard along with cresses.

The seeds of *Sinapis Chimensis* are considered by the Hindoo and Mahometan practitioners as stimulant, stomachic, and laxative. *Sinapis arvensis*, wild mustard or charlock, is one of the most common weeds in corn fields.

O'er the young corn the charlock throws a shade,  
And elapsing tares cling round the sickly blade.

The next genus we shall notice is *Nasturtium* or water-cress. *Nasturtium officinale*, formerly *Sisymbrium nasturtium*, common water-cress, is a perennial plant frequent in all the brooks and rivulets of this country. Its leaves remain green during the whole year, but are in the greatest perfection in spring. They have an acrid taste and a somewhat pungent smell when bruised. By drying or boiling they lose their sensible qualities entirely. When fresh they are extensively used as an excellent and wholesome salad. Since 1808 this plant has been much cultivated in the neighbourhood of London. Large plantations of it exist at Uxbridge, Gravesend, in Hertfordshire, and other parts of England. It has also been raised in the vicinity of Edinburgh and Paris. In its cultivation a constant supply of running water is required. The expressed juice contains the pungency and slight bitterness of the plant, and has been prescribed in doses of an ounce or two as a gentle stimulant and diuretic. It enters as an ingredient into antiscorbutic syrups and wines.

*Cardamine pratensis*, common meadow lady's smock, is abundant in moist meadows, where it is rendered conspicuous by its large bluish-coloured flowers, which are sometimes double. It is used in the same way as the water-cress. It was formerly looked upon as a diuretic, and given in doses of one or two drachms twice or thrice a day. It has sometimes been recommended in nervous diseases, such as epilepsy.

*Sisymbrium officinale*, formerly *Erysimum officinale*, common hedge-mustard, is another indigenous plant found in waste places and by way sides every where. The leaves of this plant do not possess the pungency of those of the other cruciferous plants. They are slightly acid, and are employed as tonics. The herb is used by singers to cure hoarseness and strengthen the larynx.

*Brassica oleracea*, sea-cabbage, is the origin of the common garden cabbage, of which there are nume-

rous varieties, such as, cavalier cabbage, Savoy cabbage, Brussels sprouts, early dwarf cabbage, sugar loaf cabbage, red cabbage, cauliflower, and broccoli, &c. (See articles BROCCOLI, CABBAGE, and CAULIFLOWER.) Cabbage was formerly employed as a remedy in diseases, but is now confined entirely to domestic uses. In Germany it is made to undergo a degree of fermentation, and forms what has been denominated *Sauer Kraut* or *Chou-croulé*. The red variety of cabbage is sweet and mucilaginous. It is used for pickles, and has been prescribed in chronic inflammations of the respiratory organs.

*Brassica napus*, rape or cole seed, is cultivated on account of the oil produced by its seeds, which, after being pressed, are made into cakes, and are used as manure, or for feeding cattle. The oil is used for lamps and domestic purposes.

*Brassica campestris*, grows spontaneously in the fields all over Europe, and is also extensively cultivated. There are several varieties of this species, among which may be mentioned the *rutabaga*, or Swedish turnip.

*Brassica Rapa* supplies the common turnip, so abundantly cultivated both in gardens and in fields.

*Raphanus sativus*, common radish, was originally a native of China and southern Asia, but has now become naturalised all over Europe. There are sixteen or twenty varieties known to gardeners. Some of these have globular turnip-like roots, and a rose or white colour externally, others have elongated, spindle-shaped roots, while a third set are known by their black and wrinkled exterior, and their extremely pungent taste. The latter are denominated black or Spanish radishes.

*Sepidium latifolium*, broad-leaved pepper-wort, has a hot acrid taste, and produces a redness of the skin when applied to it. It is a powerful antiscorbutic.

*Lepidium sativum*, common cress, is a well known salad. The seeds are sometimes made to germinate on cloth or wool moistened with water, or a solution of chlorine, and kept in a moderate temperature.

*Lepidium oleraceum* grows in New Zealand, and is prized there as a remedy for sea-scurvy. It resembles lettuce in taste, and acts as a moderate aperient.

*Lepidium piscidium* is used by the natives of the Society Islands, for the purpose of catching fish by inebrating them.

*Cochlearia officinalis*, common scurvy-grass, is abundant on the sea shore, as well as on elevated mountains in Britain. Its leaves yield a heavy volatile oil, one drop of which dissolved in alcohol is sufficient to communicate the odour and taste of the plant to a pound of wine. The plant, as its name implies, is antiscorbutic.

The roots of *Cochlearia armoracia*, common horse-radish, have a pungent flavour, and are used as a condiment to roast beef. They are prescribed medicinally to promote the flow of saliva, and have been recommended in cases of palsy of the tongue. An infusion of them in cold milk forms a safe cosmetic.

*Crambe maritima*, sea kale, is a native of the sea coast in several parts of Britain, and is frequently cultivated in gardens. When blanched it is esteemed as a culinary vegetable.

*Isatis tinctoria*, dyers' wood, is scarcely indigenous in Britain. It is cultivated on account of the dye, which is produced from its leaves, and which is used as a substitute for indigo. In consequence of the cheapness of the latter, the cultivation of woad is no

longer profitable. The ancient Britons used this plant to paint their bodies of a blue colour.

*Camelina sativa*, gold of pleasure, is cultivated in Germany, on account of the oil which it yields.

The seeds of *Erysimum cheiranthoides* are used by country people to destroy worms.

The dried root of *Dentaria diphylla* is used by the Americans instead of mustard, under the name of pepper root.

*Barbarea Quecœ*, early winter cress, is the American or Belleisle cress of gardeners.

Without dwelling longer on this extensive family, and attempting to notice all the species which are prized in the kitchen or the flower garden, we think that we have already sufficiently illustrated its properties, and shown its importance and value among the other vegetable tribes.

**CRUSTACEA.** One of the three primary divisions or classes into which articulated animals provided with articulated legs, are divided. They are distinguished by having the head generally confounded with the thorax, and respiring by branchiæ or gills placed at the sides of the body, beneath the hard covering or shell in which they are encased. The larger and better known species are those marine animals known under the ordinary name of shell-fish, and in the Linnæan system they composed two genera alone in the apterous order of insects, namely, *Cancer* and *Monoculus*. They are a group of animals hitherto but little attended to, either as regards their structure or habits, although several observers stand out in opposition to this observation. Thus Aristotle devoted a chapter to their history, in which much fabulous matter is of course introduced; and in the time of Hippocrates, a certain number of them were known as useful in medicine. Rondeletius, Belon, and Gesner, &c. published various descriptions of them, illustrated by rude figures; but it is to Swammerdam, Willis, and Roesel, that we are indebted for the first attempts to illustrate their organisation. Brisson, perceiving the impropriety of allowing these animals to remain amongst the true insects, first separated them, forming them—together with the *Myriapoda* and *Arachnida*—into a class intermediate between fishes and insects, thus taking the first step towards a natural distribution of the articulated animals. Fabricius and Latreille, by accumulating many valuable materials relative to them, assisted greatly towards the same end, but it is to the immortal Cuvier that we are indebted for the first separation of the *Crustacea* as a class within its strict limits.

Since this period Lamarck and Leach, as well as Latreille, occupied themselves in an especial manner towards the elucidation of this class, and formed its contents into various natural groups. Jurine, Straus, Shaw, &c., by their microscopic investigations, have greatly assisted in diffusing a knowledge of the smaller animals, whilst Savigny, Audouin, and Milne Edwards, have studied with great success the oral and internal anatomy of the *Crustacea*. In our own country the recent observations of Drs. Johnstone and Fleming, and the beautiful work of Mr. J. V. Thompson, have shown that the subject is not neglected amongst us; and very lately another observer has entered the field, S. Hailstone, junr., esq., whose descriptions of various species found on the southern coasts of England, published in the Magazine of Natural History for May, 1835, prove him to be no indifferent naturalist.

The *Crustacea*, regarded under the different relations exhibited by their organisation, ought unquestionably to occupy an elevated range in the annulose sub-kingdom. They ought not, indeed, to be far removed from the *Arachnida* and insects, which, like themselves, have a symmetrical body encased in a hard corneous covering, performing the offices of an external skeleton, and with articulated legs, eyes always apparent, sexes distinct, &c. They are, however, evidently much farther removed from the *Annelida*, in which the body is destitute of true articulated limbs, the eyes wanting, and the generation often hermaphrodite. These last, indeed, in many respects inferior both to the *Crustacea* and *Insecta*, seem to be more nearly allied to the intestinal worms, and *Epizozoa*. With respect again to the fishes with which they are vulgarly associated, their relations are very trifling indeed; but with the mollusca, especially such as the *Cephalopoda*, there is much greater affinity, so that they might naturally be placed after them in the series of animals; but as we find other mollusca, such as the *Gasteropoda* and *Acephala*, still less perfectly organised, we should either be compelled to introduce the *Crustacea*, in the midst of them, or to place the mollusca either after the entire group of annulose animals, as the ancients did, or before the *Crustacea*, as the more recent zoologists have done; and this latter step is confirmed by the observations of Latreille, who has proved the existence of the great affinity between certain of the least perfectly organised fishes, and the most perfectly organised mollusca, as the *Cephalopoda*.

The following are the characters by which the animals of this class are distinguished from the other annulosa. Animals destitute of internal vertebræ having white blood; the body divided into various segments (differing in number), encased in a crustaceous envelope, and provided with articulated legs, respiring by means of branchiæ or branchial plates, ordinarily annexed to the base of the legs or lower jaws, having a distinct heart, furnished with visible vessels, with legs, of which the number is generally five or seven pairs, and always destitute of wings; head generally confounded with the thorax, furnished with two pairs of antennæ, and a pair of mandibles (often palpi-gerous); two pairs of lower jaws, and three pairs of foot-jaws (the two posterior pairs of which are transformed into two additional pairs of legs, when there are seven pairs of the latter organs); mouth also, furnished with an upper and lower lip, or rather a tongue; the external pair of foot-jaws (see figure of the underside of the body of *Carcinus maenas*, vol. i. p. 722,) performing the office of a lower lip; eyes two, faceted, often borne upon footstalks; sexes distinct; sexual organs placed either at the base of the legs or the extremity of the body.

The class which we are now considering may be considered as taking the place in the ocean which insects occupy on land. They are very varied in their forms, as well as size, some of them being in fact the giants of the sub-kingdom to which they belong, whilst others are of a microscopic minuteness. Some species are of a globular or oval shape, others square, whilst

a few are linear and elongated, some again have the body quite flat, others are compressed, and in a few the covering of the body, instead of being hard and crustaceous, exists in a softened and membranaceous state.

These animals possess the ordinary senses which the inferior animals are gifted with, although, from the great modification in their structure, as compared with that of the vertebrated higher animals, it is difficult, and, indeed, often impossible for us to assign them to their legitimate organs. That their taste is evident from the fact that they are not indifferent to the kind of food which they meet with, and which, indeed, they seek with much assiduity. The very complex organisation of their mouths, the development of which far surpasses that of insects, must doubtless be regarded as affording the seat of this sense. The organs of sight are very distinct, in the greater number existing as faceted eyes, borne upon footstalks, often of a very great length, as in *Podophthalmus*; often, however, they are sessile, that is, not elevated upon the surface of the head or shell. The structure of the eyes of these animals has lately been studied very minutely by M. Muller, (Ann. Sc. Nat., July 1829). The sense of touch, from the hard envelope in which these animals are encased, must in all probability be greatly diminished, especially in the more crustaceous species. The circumstance that they are provided with two pairs of antennæ, as well as several pairs of palpi attached to the jaws and foot jaws, seems to favour the opinion, that this sense is transmitted by means of these organs. The sense of hearing has not been distinctly proved to be possessed by these animals; it has, however, been supposed that the seat of this sense was placed in an excavation observed at the base of the external pair of antennæ in certain of the larger species, as the lobster, &c., in which cavity it has been stated, that a small sac filled with fluid exists, in the midst of which a nervous thread was fixed; it is certain, however, that the aperture of this cavity is closed by a membrane, and that in some cases there exists (as in *Maisia*) a small crustaceous organ or moveable operculum, the use of which appears to be to distend the membrane which shuts the orifice. Of the distinct existence of the sense of smell we are also equally ignorant, although from analogy we are led to believe that it is possessed by these animals. Its seat is also unknown, although Rosenthals and Robineau considered that it existed in a pair of small orifices at the base of the internal pair of antennæ.

Annulose animals having the vertebræ as it were external, are necessarily prevented from undergoing a similar mode of growth to that which distinguishes those animals which, having the vertebræ internal, acquire an increase of the external softer portion of the body, without any obstacle to its addition; but the solid shell of the crab may readily be conceived to be an unsurmountable obstacle to its growth, which nevertheless takes place from year to year. Nature, therefore, has removed this obstacle in a curious manner. The caterpillar casts its skin several times before it becomes a chrysalis, the crab in like manner undergoes an annual moulting; but it may well be conceived that the complete shedding of a crustaceous envelope like that of the crab, must be a far more remarkable operation than the slipping of a thin membranous skin like that of a caterpillar. The principle is, nevertheless, the same in both cases. When, however, we consider that not only the shell but also

\* A celebrated zoologist recently requested a friend who was going a long sea-voyage, to bring him home all the fishes he could procure. "Yes," was the reply, "I will catch you all kinds, from a whale to a shrimp;" neither of which, as every person acquainted with the slightest outlines of zoology well knows, are fishes.—We mention this anecdote to show that a little knowledge here would not have been a dangerous thing.

the covering of all the most delicate organs, such as ten eyes, antennæ, and even branchiæ is shed at the same time, we find not less grounds for astonishment and wonder. The minute *Crustacea*, whose growth is very rapid, change their coats at very short intervals of time. Thus Jurine observed that the young *Daphniæ* moulted eight times in seventeen days, but amongst the large species, such as the crabs and lobsters, this only occurs once a year. When, therefore, at the end of the spring, the *Crustacea* having previously obtained such an increased supply of food, as to make their shells too confined for the increased size of their internal organs, they cast their entire skeleton as we may term it. Previous to doing this, they appear sick, languid and restless, seeking some secluded place, in which they may securely remain until their new covering shall have attained a sufficient consistence. In casting their shells it is difficult, at first sight, to conceive how it is possible that the enclosed claw, for instance, can be so completely drawn out of the old covering, through the narrow part by which it is attached to the body, so as to leave the shell of the claw entire, and attached to the exuvia of the body, in which state they are constantly found. The new shell, however, is at first quite soft and membranaceous, so that we may thereby account for this circumstance, without adopting the opinion of the fisherman, that the lobster pines so much before moulting, that the flesh of its large claw is reduced to the size of a goose quill, which enables, it to draw its parts through the joints and narrow passage next the body. Still it is evident, that the forcing of the inclosed claw, even if ever so soft, through so narrow a passage must be exceedingly painful. It is to Reaumur that we are indebted for our knowledge of the precise circumstances connected with this curious phenomenon, that distinguished author having imprisoned several crayfish about to moult in pots pierced with holes placed in running water. It is said that it is easy to perceive when the period of moulting is approaching, by pressing the backs of the animals, when the shells yields readily to the pressure of the finger, not offering that resistance which is common to them. The animals then beat their legs with violence against each other, the body is in a complete agitation, the membranes between the segments being greatly distended, so that the shell is raised considerably from the abdomen, the membrane bursting which connects them. By degrees the entire shell and external covering is shed; and in the course of two or three days, or even twenty-four hours, the new skin has acquired its proper consistence.

Another circumstance of a still more remarkable nature, occurs in the animals we are now treating upon; namely, the reproduction of the claws and legs when accidentally broken off. In some species, indeed, the limbs are so slightly attached, that the least touch causes them to shed them. In like manner it is said that lobsters fear thunder, and are apt to cast their claws on a great clap, and that they will do the same on the firing of cannon; so that when men of war meet a lobster boat, a jocular threat is used, that if the master does not sell good lobsters they will salute him. In the course of a day or two the naked skin exposed by the wound, is found to be covered with a reddish pellicle, which soon assumes a convex surface, grows longer, becomes conical, increases in size, and splitting, exposes to view a soft body, composed of the same number of parts as had been lost.

This soon gains the consistence of the remainder of the body, but never acquires the size of the limb lost although at every subsequent moulting of the skin, its size increases more rapidly than that of the rest of the limbs.

This curious phenomenon involves, in a singular manner, the principles upon which the moulting of the skin of the annulosa takes place. We are taught that the wings of a butterfly exist in the caterpillar state, and that the legs of the larva of a grasshopper envelope the legs of the perfect insect; if, therefore, we admit the theory of Swammerdam, founded upon these statements,—that every larva at its first exclusion, contains within itself the germ of the future imago and of all its envelopes, which, successively presenting themselves, are thrown off, presenting to view the next internal envelope, we shall be compelled to establish another theory for the *Crustacea*, similar to that of Dr. Heroldt—that the successive skins of the larva, pupa, case, imago, and its parts and organs, do not pre-exist as germs, but are formed successively from the rete mucosum. Reaumur has, indeed, attempted to explain the causes of this reproduction of limbs; inquiring, if, at the base of each leg, there may not be a provision of new legs, as in children there is a tooth under the milk tooth! We are surprised that so acute a reasoner as Reaumur should not have perceived the incorrectness of such a supposition. It is perfectly natural that the milk teeth are one day destined to fall, and it is natural that their places should be occupied by fresh teeth, which are accordingly provided. But it is perfectly unnatural—merely accidental—that the lobster should lose its claws; and it is equally unnatural to suppose, that nature should have provided a series of organs which, in the majority of instances, would be totally useless, depending only upon accident for their casual development.

The female crustacea, after impregnation, deposit a vast number of eggs, which, in many instances, are retained beneath the abdominal portion of the body, whilst in some, as in the opossum shrimps (*Mysis*), the sea wood-lice (*Isopoda*), they are retained in a kind of sub-thoracic pouch, and in others they are placed in a membranaceous bag, or pair of bags, dependent from the base of the abdomen, as in the *Cyclops*; *Branchipus*, &c. It has been generally stated in all works upon this class, that with a very few exceptions, the young, when hatched from the eggs, closely resemble their parents in form; these exceptions occurring in *Cyclops*, the young of which were regarded by Muller as belonging to two distinct genera (*Amyndus* and *Nauplius*), *Argulus*, and *Branchipus*. Indeed, Dr. Leach, one of the chief investigators of this tribe of animals, has assigned it as one of their principal characters, that they undergo no *metamorphosis*. Mr. J. V. Thomson of Cork has, however, lately published a series of memoirs, in which he has announced as an "important discovery, that the greater number of the crustacea do actually undergo transformations. The circumstance of the crustacea being supposed to pass through no intermediate form, has been brought forward heretofore as one of the arguments for their separation from insects; but although the fallacy of that opinion may diminish the number of characteristics which distinguish these two tribes of animals as distinct classes, there yet remains those depending on the anatomical structure of their respiratory and circulating systems, which are

quite sufficient to render their separation permanent. It may also be observed that the changes presented to our notice in the crustacea, are quite peculiar, and of a totally different description from those of insects." Mr. Thomson then proceeds to notice the different extraordinary animals known to naturalists under the name of zoea, which, from their peculiar structure, had greatly perplexed systematic crustaceologists, and states, "It will no longer be a matter of surprise that all the leading naturalists of the present day should have been at a loss how to dispose of zoea in their arrangements of the crustacea, when it is known that this singular type is not a perfect animal, but merely the larva or imperfect state of the crab! and not as had been imagined an animal *sui generis*." Subsequently our author states, amongst other circumstances, that he, "succeeding in hatching the ova of the common crab, during the month of June, which presented exactly the appearances of *Zoea Taurus*, with the addition of lateral spines to the corselet, the crustacea then indisputably undergo a metamorphosis, a fact which will form an epoch in the history of this generally neglected tribe, and tend to create an interest which may operate favourably in directing more of the attention of naturalists towards them\*." And as the zoeas are aquatic animals furnished with swimming organs, Mr. Thompson concludes that the circumstance of the young of the crustacea being thus natatory, enables us satisfactorily to account for the annual migration of the land crabs of the West Indies to deposit their eggs in the water. We have thus given Mr. Thompson's observations at some length, because the facts, if fully established, are highly interesting, and sufficient to raise Mr. Thompson to a very high rank amongst naturalists. It is proper, however, to state, that Dr. Rathke has, in a series of microscopic observations, far more elaborate than any hitherto published by Mr. Thompson, clearly shown the gradual development of the cray-fish within the egg, and which, upon bursting into life, possesses all the form of its parent, whilst the Rev. Lansdown Guilding has expressly stated that the land crabs do not undergo any metamorphosis (Mag. Nat. Hist., May, 1835), a statement which we can fully confirm; thus, two examples in the great divisions of *Brachyura* and *Macroura* are shown to militate against Mr. Thompson's assertion, that the crustacea universally undergo metamorphosis; and, as the organisation of those two animals is so completely analogous to that of the common crab (the young of which Mr. Thompson affirms to be a zoea) and the rest of the *Decapoda*, we think that analogy strictly warrants us in assuming that Mr. Thompson must have fallen into some fundamental error in his observations. We look forward, with great interest, to his promised continuation of these memoirs, which have been too much neglected by naturalists.

Various modes of distribution of this class have been proposed by different crustaceologists, which it would occupy too much space to detail; we shall, therefore, proceed to give a short sketch of that which appears to us to be the most natural hitherto published, namely, that by Latreille in the second edition of the *Régne Animal*, premising only that we have omitted the fossil tribe of *Triobites*, which will form a distinct article, and that the distribution of Mr. Edwards, founded primarily upon the manducal-

tory or suctorial nature of the mouth, appears to us to be less natural than that given below.

#### CLASS CRUSTACEA.

Section 1. MALACOSTRACA. Shell of a solid consistence; legs ten or fourteen; mouth with a labrum, two mandibles, four maxillæ, six or ten (according to the number of legs) foot jaws.

Sub-section 1. PODOPTHALMA. Eyes on footstalks.

Order 1. *Decapoda*. Legs ten; foot jaws ten; branchiæ in a cavity at the sides of the thorax; divisible into two sub-orders.

*Brachyura* (short tailed crabs—See BRACHYURA).

*Macroura* (lobsters, &c.—See BRACHYURA and MACROURA).

Order 2. *Stomatopoda*. Branchiæ not inclosed beneath the shell at the sides of the thorax; legs more than ten.

Sub-section 2. EDRIOPHTHALMA. Eyes not elevated on footstalks.

Order 3. *Amphipoda*. Body compressed; mandibles palpigerous. See AMPHIPODA.

Order 4. *Læmodipoda*. Abdomen rudimental, with only the rudiments of one or two pairs of appendages. See CAPRELLA.

Order 5. *Isopoda*. Body depressed; abdominal appendages flat and plate like; mandibles not palpigerous.

Section 2. ENTOMOSTRACA. Shell not solid; legs variable in number; mouth very variable.

Order 6. *Branchiopoda*. See this article and its divisions.

Order 7. *Pecilopoda*. Mouth suctorial, or destitute of mandibles and maxillæ, but defended by the ambulatory legs which perform this office. Divisible into the sub-orders *Xiphosura* (or king crabs), and the *Siphonostoma* (or fish parasites). See CALIGIDES.

As these kinds of tabular sketches are best elucidated by references to figures, we will direct our readers, for an illustration of the *Decapod Brachyura* to Vol. I. p. 722, for a figure of *Carcinus maenas*; of the *Decapod Macroura*, to p. 167 of this volume, for a figure of the *Cray-fish*; of the *Amphipoda*, to Vol. I. p. 95, for a figure of *Gammarus Palix*, by mistake called *Pernys*, which is the *Corophium longicorne*; of the *Læmodipoda*, to Vol. I. p. 691, for a figure of *Caprella Phasma*; of the *Isopoda*, to Vol. II. p. 25, fig. 2, representing *Armadillo vulgaris*; of the *Branchiopoda*, to Vol. I. p. 626, representing the *Brine Shrimp*; and we here figure the *Argulus foliaceus*,

1, the animal magnified; 2, one of the large anterior sucking feet; 3, the rostrum; 4, natural length.

belonging to the order *Pecilopoda* (sub-order *Siphonostoma*), an account of the habits of which will be found under the article CALIGIDES. The remaining classes *Stomatopoda* and *Xiphosura*, will be illustrated in subsequent articles.

CRYPTANDRA (Smith). A genus of curious shrubs from New Holland. Class and order *Pentandria Monogynia*, and natural order *Rhamneæ*.

**Generic character:** calyx of five sepals; corolla tubular, five-cleft, in the throat of which there are five hollow scales concealing the stamens; stigma trifid; capsule three-valved, seeds three. These plants were introduced into our collections twelve years ago; and thrive well in the greenhouse, potted in loam and moor earth. They are propagated by cuttings without difficulty.

**CRYPTODIBRANCHIATA** (De Blainville; CEPHALOPODA, Lamarck, Cuvier; SEPIA, Linnæus). These molluscs form the first order of the modern system of Malacology—or that science which treats of soft bodied animals, without bones or articulations; some, however, possessing internal testaceous portions, and by far the greater number external shells or coverings, varying in an infinite degree of form; the intermediate links of affinity between these singularly organised creatures, mark those interesting changes which take place throughout the system, many of them to be satisfactorily proved by analogous reasoning, to be the consequence of necessity arising from peculiarity of circumstance or situation.

This order of molluscous animals, as far as is yet known of them, includes species of the type, possessing the highest and most perfect organised parts and faculties of all the mollusca; they enjoy all the animal functions of seeing well, hearing, moving with ease and rapidity from one spot to another, of pursuing and seizing their prey; and they even appear to possess something like a feeling of attachment to each other. It having been remarked by an accurate observer of nature, whose observations we have frequently been permitted to quote, on these animals and molluscs in general, that he has remarked and repeatedly made the experiment of placing other molluscs with members of the *Cephalopoda*, and always found they were driven from their society, and obliged to congregate in a different part of the same space to which they were confined; observing also, that when one of these intruders presented itself, or had wandered out of its assigned limits, the *Common Cuttle fish* particularly, exhibited, as it were, immediate signs of uneasiness. That peculiar breathing kind of motion, which resembles the exhaustion and filling of their bladder-formed bodies, became more rapid; their tentacular appendages much agitated; and, in a few seconds, the whole of the family were in motion, occupied in driving the stranger from amongst them, all united as it were in a common cause against the supposed enemy. Their movements, however, upon this occasion were by no means rapid; on the contrary, they seemed guided by a regularity of purpose generally understood to themselves, and it might almost be imagined directed by a recognised commander—they never assailed the intruder, each after his own fashion surrounding it promiscuously, but clearing a passage, left ample space for retreat; and then, from the nearest to the most distant point, they closed in and prevented its intrusion. In this movement much purpose was exhibited, for the *Sepia* did not form themselves into a solid mass, but each of them appearing to have a place allotted to it, moved nearer to the sphere of action, with something like regularity; each one prepared and in motion, but not going far from the spot in which it had been reposing: the impulse of alarm appeared general, but rather to excite caution than anger, though the result invariably was the same, that of precluding the stranger from entering into their congregation. These observations were made on a

part of the Dutch coast, where some acres of marsh land were overflowed each tide; and the situation being, doubtless, favourable to these creatures, their numbers were countless—the whole space exhibiting a palpitating moving mass of creatures, in some parts so closely packed as to have the appearance of forming but one animal. Professor Kops, of Amsterdam, visited the spot in the summer of 1816; and his interesting remarks on this occurrence form a paper read at an academic meeting in Holland. The following year, however, the same spot was deserted, and not a single sepia to be seen there.

The body of the animals of this order are enveloped and partly free, in a very thick mantle, expanding into a wide opening at its anterior side; the edges free, and detached all round, looking like a sack or opened bladder, without any trace of muscular abdominal disc, or of a foot; this body is most generally naked, either unprovided with solid internal parts, or inclosing a shell or other hard substance; sometimes provided with an external substance or testaceous portion, covering or sheathed in the body. This is never composed of two opposite valves, its shape is extremely various; it is placed dorsally, and serves as a shield or protection to some of the more delicate organs. The animal is completely inarticulate, provided with a very large head, more or less projecting; this presents four or five pairs of conical tentacular appendages attached at their base to a kind of skull which envelops the brain, and are furnished with suckers used for prehension: these arms are disposed in a circular order, in the form of a coronet. The mouth is altogether anterior, elongated or tubular; armed with a large pair of horny teeth in the form of a parrot's beak, acting vertically against each other. The mantle is diversified; the gills or organs of respiration various; rarely symmetrical, lateral, and concealed in the sac; the circulation is double, one particular, the other general; the heart unilocular, sometimes with the auricles divided, and very distant; no medullary cord along the body, but provided with a few scattered nerves and ganglions.

This order includes the genera *Octopus* in the first family, and the second family *Decacera*, contains the *Loligo* and *Sepia*. They are abundantly found in the seas of all countries, and probably larger and more numerous in those of warm latitudes, where marvellous stories are related of their gigantic structure; they, however, are so much involved in ignorance and mystery, resting only on the uncorroborated testimony of incompetent judges, that though we are not in a position to contradict them positively, we are unwilling to receive them as well-established facts. Not that we absolutely reject the possibility of much we have heard respecting them being true, for every instant of our existence brings to light new discoveries in the animal kingdom, elucidating the phenomena of nature; and we have constantly had occasion to remark, that marvellous as many of the tales of olden times at first appeared, they more or less, have originated in a simple matter of fact, distorted or magnified by subsequent narrators, and disguised at all times by ignorant credulity, which eagerly adopts that which cannot easily be disproved. We are, however, as we have just stated, cautious without being incredulous; never forgetting that Bruce's *Abyssinian beefticks* drove him from society, and broke his heart by slow degrees. We have also the assertion before our eyes of a recent delightful writer, who says he is really

fearful that his truth would be doubted if he were to relate some of the scenes he had witnessed; and he has actually confided his information to such only as know his integrity, leaving future travellers to confirm his assertions. We can fully appreciate this feeling, and honour it; but were all mankind to be actuated by similar delicacy, no progress would be made in elucidating the phenomena of nature—science must cease to advance, and ignorance become perpetuated. First impressions are readily received, and frequently remain deeply impressed; but a well constituted mind hesitates to admit them, without having minutely weighed the mass of evidence for or against them, and exercising a sound discretion as to its worth.

It would be travelling far out of our prescribed path, to enumerate the thousand instances we might easily adduce, in which a description of nature and her operations would be treated at first sight as the idle dream of a disturbed imagination, or a tale of poetic fancy. This applies to every portion of creation, but to none more universally than to *entomology*; in which the insect transformations, their habits, and their ordained purposes, have become additional proofs of omnipotent wisdom, through the laborious investigations of a host of eloquent writers on the subject, from an early period, down to those of the venerable Kirby and others of our own time. With such examples, we dare not reject any thing as impossible to the Architect of nature; but we are slow to give implicit credence to all we hear, unsupported by the clearest concurring testimony.

*Cephalopoda*—the name given to these animals by Lamarck, Cuvier, and other modern naturalists—is derived from two Greek words, implying the feet so called, being placed on the head. *Cryptodibranchiata* means the animal's two branchiæ being concealed, *Cephalopod* is, however, the commonly received term, and is more expressive, as indicating a character which readily strikes the senses, without requiring any additional information from anatomical examination, to guide the first step towards a system of classification.

**CRYPTOCEPHALUS** (Geoffroy). A genus of coleopterous insects of considerable extent, belonging to the family *CHRYSOMELIDÆ*, which see; having the antennæ long and slender, head small and vertical, the body short, thick, and cylindric, and legs formed for walking. They are of a small size, seldom reaching half an inch in length. Their form is not elegant, but they are compensated by the beautiful colours and markings with which they are adorned. They are found upon flowers in the hot sunshine, and feed, both in the larva and perfect state, upon vegetable matters; destroying the young buds, they do not cut, but macerate, and occasion them to dry up and fall. When disturbed they have recourse to artifice by folding their antennæ and legs close to the body, and counterfeiting death. At a late meeting of the Entomological Society of France a larva found in an ants' nest, enclosed in a solid case, was described, and which was considered to be that of a species of this genus. M. Géné of Turin has also published some interesting observations upon the larvæ of the *Cryptocephalus*. Dejean, fourteen years ago, enumerated seventy species, since which the number has greatly increased. There are about twenty inhabitants of this country, amongst which the type, *Chrysomela sericea* of Linnæus, is one of the prettiest species, being of a fine silky golden green colour with black

antennæ; it is about one-third of an inch long, and is found upon umbelliferous plants in June.

**CRYPTOSTEGIA** (R. Brown) is an East Indian genus, belonging to *Pentandria Digynia*, and to the natural order *Apocynææ*, according to Sweet and Sprengel, but to *Asclepiadææ*, according to Lindley. The *C. grandiflora* is a beautiful climber, and thrives well in the common mixture of loam and moor earth, and may be propagated by cuttings struck in sand.

**CRYPTOSTEMMA** (R. Brown). A genus of syngenesious annuals from the Cape of Good Hope, and belonging to the natural order *Compositæ*. The species require to be treated like tender annuals, that is sown on a gentle hot-bed, and, when strong enough, planted out in the open borders in May. They are handsome flowers, and deserve to be in every flower garden.

**CRYPTOSTOMA** (Leach). A mollusc whose body is tongue-shaped, in a great degree formed by a very long and thick foot, narrower in front, channelled on both sides, and extending considerably beyond the twisted visceral mass, which is very small, rather convex on the upper side, and about a third of it covered with an internal shell, extremely similar in every respect to the *Sigaretus* properly so called; the mouth is very small and concealed beneath the anterior and superior fold of the foot, towards which its four grooves diverge; from this very singular position of the mouth the genus has been named. There are two tentacula pedunculated at their base, eyes not ascertained, and one great branchial comb. There are only two species of this genus described, both from India, but it is not improbable some species of Lamarck's genus *Sigaretus* will be discovered to belong to it. It is placed in the second class *Paracephalophora*, second order *Chismobranchiata*, family *Lamâcuca*.

**CRYPTOSTYLIS** (R. Brown). A genus of New Holland gynandrous plants introduced into this country about ten years since. Like other *Orchidææ*, the flowers are curiously shaped, and of a dark brown colour. The bulbs or rather tubers are connected in a bundle, and thrive best planted in a frame, or, according to Mr. Sweet, on a warm border, where, if they are only protected from frost in winter, they will survive and flower finely. Their favourite soil is turfy moor earth, loam, and sand.

**CTENISTES** (Reichenbach). A very minute genus of coleopterous insects belonging to the family *Pselaphidææ*, having the palpi as long as the head, with the extremity of the second, third, and fourth joints armed laterally with an acute spine. They are nearly allied to *Bryaxis*.

**CTENOPHORA** (Meigen). A handsome genus of dipterous insects belonging to the section *Nemocera* and family *Tipulidææ* or crane flies, distinguished by having the antennæ beautifully feathered in the males; these organs moreover are thirteen-jointed in both sexes. In other respects they are very nearly allied to the daddy-long-legs, or true tipula. They are found in damp situations, amongst herbage, &c. The larvæ resemble those of the *Tipulææ*, and live in the decaying matter of trees, &c., where they change into pupæ, having the body armed with hooks. There are eight British species, the type being the *Tipula pectinicornis*, Linnæus.

**CUCKOO** (*Cuculus*, auctorum). A most interesting genus of zygodactylous or yoke-footed birds, or of those which have the toes situate two before and two

behind. This, however, by the way, although very generally accepted, is by no means a satisfactory division, as it contains a great variety of birds which have otherwise very little or no resemblance: the cuckoos, the parrots, the woodpeckers, and the toucans, together with several other very dissimilar forms, are here brought together and included in one order, which have hardly a single character in common; and even the foot, which forms the sole basis of the classification, is extremely different in many of the genera, as a comparison of this organ in the woodpeckers and parrots will abundantly show. It has been commonly designated a *climbing* foot, but in some of the families it is never used in this manner; and, in the birds which we are now about to describe, the chief purpose of this conformation appears to be, to give additional firmness to the grasp, the centre of pressure being, in the cuckoos, exceedingly forward.

In this genus the bill is somewhat compressed, of moderate length, or about as long as the head, and slightly curved; the lower mandible following the curve of the upper; the nostrils are basal, round, and margined with a prominent and naked membrane; the gape of the mouth is very wide, but the gullet is small, in the common species not large enough to admit the finger. The wings are of mean length, pointed, having the first quill-feather short, and the third longest; tail rather long, always more or less wedge-shaped, and strongly fortified by coverts. The tibiae are clothed with long feathers, as in many of the diurnal birds of prey; the tarsi short and feathered a little below the joint; the two front toes are joined together at the base, and the two hinder ones entirely divided, the outer hind toe being partly reversible. The character of the plumage is firm, and they carry an immense deal of feather in proportion to their size, and the hues of the more typical species are, in general, rather sombre, mostly ash-colour or dusky on the upper parts and breast, with the under parts lighter and barred across; in the immature state they incline more to rufous, and are everywhere transversely barred with a darker colour; this latter being also the mature plumage of one or two of them. A few small species, however, from the Cape, nearly allied in some respects to the former, have the upper parts of the most brilliant emerald green, these being among the most truly splendid of the feathered race.

The true cuckoo to which the typical appellation *Cuculus* is now restricted, are all natives of the eastern continent, but America produces species very closely allied in structure to these, which we shall have occasion to mention as we proceed, but which differ too essentially in their general economy to be included in the same generic division. One of these, the *Coccyzus Carolinensis*, having been driven out of its regular line of migration, and winged its way across the wide Atlantic, has now occurred several times during the autumn months in this country, and has consequently found its way, as an accidental straggler, into the long catalogue of species which occur in the British islands.

The common European cuckoo (*Cuculus canorus*, or *singing* cuckoo) is a bird about the size of a small pigeon, or rather appearing of that size from the very great quantity of feathers with which it is clothed. Its bill is blackish brown, yellowish at the base; the corners of the mouth and the rim around its eyes bright orange; the irides gamboge yellow; gape orange red. Its head, neck, breast, and upper parts

are of a deep bluish grey, darkest upon the wing-coverts. The whole of the belly, thighs, and under tail-coverts whitish, with transverse black bars. Inner webs of the quill-feathers with oval white spots. Tail black, with a few white oblong spots along the shafts of the feathers, which are also tipped with white. Legs and feet lemon yellow.

The Common Cuckoo.

The above is the adult livery of the male bird; and the mature female differs only in being always more or less marked upon the breast and sides of the neck with rufous bars, somewhat similar to those of the young.

The well known vernal call note of this species, is

"Note of fear,  
Unpleasing to a married ear,"

is generally first heard in the south of England about the second week in April, sooner or later, however, in some measure according to the temperature of the season; for, if the weather continue cold and bleak, though the birds have made their appearance, their note is but very seldom repeated. This call note is, indeed, at all times very much affected by the state of the weather; during a long continuance of drought it gradually becomes more and more hoarse, till, at length, it seems to be uttered with considerable effort, and the first syllable of it is often broken into two or three; but no sooner does the wind veer to a rainy quarter, than, before even a change is visible in the sky, it immediately softens, and is pronounced quite musically and distinct. We are at present in some doubt as to whether this cry—*cuckoo*, is common to both sexes; but the writer of this article inclines rather to assume the contrary, at least, till it can be positively shown, from the examination of a female that had been heard to sing, that this really is the case: generally speaking, he is pretty confident that the hen bird does not utter the note.

There is, however, another cry, which certainly is repeated by both sexes, though most frequently by the female cuckoo; it may be expressed by the sound *cui* or *cuii*, repeated several times in rapid and continuous succession; and it is invariably uttered either when the bird is upon a tree, generally the moment before it takes wing, or immediately after, sometimes the one and sometimes the other; this note very closely resembles one or two passages in the nightingale's song, and we may always calculate upon seeing the bird flying immediately after hearing it. The other and more generally known note—*cuckoo*, is alike repeated either when the bird is perched or

as it flies across a field; sometimes, also, during the night. Some sound and accurate observations upon this species are contained in the following unsophisticated doggrel; they apply, however, only to the adult cuckoo, for the young of the year do not leave us till the month of September.

"In April,  
Come he will;  
In May,  
He sings all day;  
In June,  
He changes his tune;  
In July,  
Off he'll fly;  
But in August,  
Go he must."

The alteration of the note in June is, as we have already stated, entirely dependent upon the weather, which, at least in the south of England, where the rhymes are current, is usually very hot and dry during the month of June. Quaint and homely little sayings such as these, simple as they may at first sight appear, are often great aids to the memory, and have mostly been put together by persons of much observation and discernment. Those who study practically natural history, have very often occasion to admire and commend their accuracy.

The most curious, wonderful, and extraordinary circumstance in the natural history of this bird, and that upon which all its other peculiarities depend, is the strange, and at present quite unaccountable habit which it exhibits, of invariably depositing its eggs in the nest of some other species, at no time, nor under any circumstance whatever, constructing a nest and hatching its own eggs like other birds; the same is also said (and is probable) of the other typical species of *Cuculus*, but at present this requires some confirmation. The American and other *Coccyzi*, which, except in having rather a stronger bill, and in being a little longer in the tarsus, approximate very closely to the true cuckoos in their general structure, build nests and tend their progeny like the other feathered tribes around them. The only decided and well authenticated instance of a similar deviation from ordinary rule, occurs in the cattle-bird or cow-bunting (*Malothrus pecoris*, Swainson) of North America, a bird of the starling family, and of which a rather detailed account (chiefly taken from Wilson's American Ornithology) has already been given in its alphabetical situation in this work. That species, however, from its abundance and much greater familiarity, is easily enough studied, and its various peculiarities are all much more satisfactorily elicited than are those of the European cuckoo. The latter is one of the very shyest of the shy; its history has been much obscured by scribblers, and we are a great deal indebted to chance observers for the facts that have been brought together concerning it.

Like the American cattle-bird, the European cuckoo (as indeed might be anticipated) does not pair, nor, according to the common acceptance of the term, is it a polygamous species, but all of them live together in a promiscuous state of concubinage. Tied down by no duties of incubation, they are perhaps bound to no particular spot, but wander without control throughout the summer. This the naturalist of Selborne alludes to in one of his poetic effusions—

"And listen to the vagrant cuckoo's tale."

Yet, though it be undoubtedly difficult in places

where cuckoos are abundant to identify any particular individual, unless, indeed, it be an albino, or otherwise conspicuously distinguishable, we are inclined to think from repeated observation, that each cuckoo does generally confine itself within a certain range. The male probably locates himself in a particular situation in a spot congenial to his habits, where food is to be obtained plentifully; and if a sufficient number of the other sex there answer to his call, he probably does not wander far from the place. We have arrived at this conclusion, from having observed always a certain number of these birds in a particular spot. The female cuckoo, however, may probably sometimes wander a considerable distance when searching for a suitable nest to deposit her egg in.

Strangely enough, the number of eggs which the cuckoo lays in the course of a season, has never been very satisfactorily determined; which might easily enough be done, by dissecting a sufficient number of females during the spring and summer months.

"It is possible," says Montagu, "that some may lay two lots of eggs during their stay with us; but then we have reason to believe there is a considerable space of time between the first and second lot. In two or three females, dissected at the time they first began to lay, we could only discover four or five eggs that could possibly be laid successively; from the smallest of which, to what may be termed the secondary eggs, there was a sudden break off, not a gradual decrease of size." A young cuckoo of the preceding year (known by not having entirely thrown off its nestling feathers), which the writer of this examined on the twenty-second of May, contained in the ovary three largely developed eggs, which unquestionably would have been laid on the following consecutive days; there were also sixteen or eighteen others (besides a multitude of small ones) enlarged to the size of mustard seeds, but a competent physiologist is of opinion, that these would not have been laid the same season, their increase of size being occasioned by the determination of blood to the parts; they presented no vascular appearance, and it is probable that, after the breeding season, they would have diminished to their former minuteness†.

The cuckoo's egg is remarkably small for the size of the bird, hardly equalling in this respect that of the skylark; it is therefore somewhat in proportion to the small nests into which it is commonly introduced. Those parts, also, *quæ maribus tribuuntur*, are at all times most disproportionately small in this species, even less than in the common sparrow; but whether this has any connexion with the size of the egg is difficult to determine. The American *coccyzi*, according to Wilson, have the egg "proportionable to the size of the bird," and it would therefore perhaps be worth while to notice further the internal structure of the males of these. The egg of the common cuckoo is usually of a very oval form, of a reddish white, thickly sprinkled over and blotched with rufous and darker brown spots, which are rather more numerous at the larger end; like most other eggs, however, it is subject to some variation.

Contrary to the usual opinion, the female cuckoo appears to deposit her egg into the first suitable nest she happens to find, whatever may be the species of bird to which it belongs, whether granivorous or (like

\* W. Yarrell, Esq.

† The ovary in question is now preserved in spirits.

herself) insectivorous; and it is one of the most curious facts in natural history, that many of the smaller finches, which never themselves touch any sort of insect food, and even bring up their own young exclusively upon softened vegetable food ejected from their own craws, will, notwithstanding, rear up the young cuckoo upon caterpillars and other insects. A case is mentioned in the "Magazine of Natural History," of a young cuckoo being brought up by a pair of common linnetts; and another, in which a pair of green grosbeaks were the foster parents. In the "Field Naturalist's Magazine," also, for January, 1834, the following highly interesting fact, bearing on this subject, is recorded.—"A cuckoo was found just feathered, in the nest of a hedge-chanter. It was immediately taken from thence, and placed in a cage containing a hen canary. The birds agreed perfectly well; but what is most singular, when the proper food for the cuckoo (small caterpillars, &c.) was placed in the cage, the canary fed its young charge with that, although she herself kept to the hempseed, &c., to which she had been accustomed." It would appear, however, from the results of a great number of experiments which the writer of this has instituted upon this subject, and in which, from the great difficulty of procuring a number of cuckoo's eggs, those of the skylark were chiefly employed, as being both in colour and size somewhat similar to them, that an alien egg, surreptitiously introduced into a nest, is very frequently ejected from it by the rightful owners. The writer of this has tried this experiment upon a very great number of species; has placed the alien egg along with other eggs, has taken the latter away and substituted it singly in their place, and has placed it in many newly-finished nests, before any other eggs had been deposited in them, and he has continually observed the same result. He thinks, therefore, he may fairly conclude that the cuckoo's egg also is very frequently turned out by the birds into whose nests it is deposited. He can only thus account for the excessive rarity of its occurrence, although the birds are everywhere seen abundantly, and though he has counted upwards of fifty eggs, of different sizes, in the ovarium of a single cuckoo.

It is indeed stated by Mr. Hoy of Norfolk, a gentleman well known to naturalists as a most accurate and close observer, that "it appears to be usual for the birds, in whose nests the cuckoo may have deposited an egg before they may themselves have begun to lay, to cast out the cuckoo's egg;" and as that gentleman has bestowed particular attention upon the phenomena of this interesting bird, he has doubtless observed some instances to warrant this remark. He mentions, however, one case in which the contrary was observed. "On one occasion," he says, "I had observed a cuckoo during several days anxiously watching a pair of wagtails building; I saw the cuckoo fly from the nest two or three times before it was half completed; and at last the labour of the wagtails, not going on, I imagine, so rapidly as might be wished, the cuckoo deposited its egg before the lining of the nest was finished. The egg, contrary to my expectation, was not thrown out; and on the following day the wagtail commenced laying, and as usual the intruder was hatched at the same time with the rest, and soon had the whole nest to itself." This instance seems to favour the opinion that the cuckoo possesses the power of retaining her egg in the oviduct considerably longer than is the case with birds in gene-

ral; and it is possible, as has been suggested to the writer of this article by a distinguished physiologist, that the nervous excitement of the bird, whilst wanting to lay, may have the effect of preventing the immediate development of the egg next in succession. There is not the slightest reason, however, to suppose with some that the egg is ever quickened in the oviduct by the heat of the parent bird; for were such ever the case, it would of course be necessary that it should be deposited in a nest upon which the owner had begun to sit, which the cuckoo of course would be unable to do, as she never drives a bird off its nest, but sneaks into it during its absence. It is hardly necessary perhaps here to remark, that after the vital action within an egg has once commenced, a very short suspension of the necessary degree of warmth is sufficient to destroy the embryo. No instance, however, has been yet recorded of the cuckoo's egg having been found addled.

The common cuckoo's egg has been known to occur in the nests of the following British species, viz., the blackbird, songthrush, skylark, green grosbeak, linnet, chaffinch, hedge-chanter, different pipits and wagtails, yellow and reed bunting, redstart, robin, reed warbler, hedge warbler, and grasshopper warbler; but in at least nine cases out of ten, it is found either in those of the common or the shore pipit (*Anthus pratensis* and *A. obscurus*), or in that of the pied water-wagtail (*Motacilla domestica*, *M. alba* of Linnæus), and somewhat less frequently in that of the hedge-chanter (*Accentor modularis*); the chief reason of which, in the opinion of the writer of this, is that these birds are not so much in the habit of turning out an alien egg as the others are; he has known, however, the hedge-chanter to eject a lark's egg that was placed along with its own, and also to eject another which was placed alone in the nest, its own eggs having been taken away. Some birds, as the blackcap, most usually forsake a nest into which the egg of another species had been introduced. Others will turn out the alien egg, and even then desert their nest.

Nothing is more certain than that the number of cuckoo's eggs that are found is out of all proportion small, considering the number of birds that are heard and seen. Unlike all other birds also, the number of young cuckoos that are ever seen in autumn is very considerably smaller than that of the old ones; although, from their being very much buffeted and persecuted by swallows and many other small birds, they are little likely to escape observation. It is, therefore, very difficult to conceive how the species is continued so abundantly; perhaps they live a great number of years, but the following fact seems hardly to warrant this supposition, that there is not, when they arrive in spring, the same proportion of individuals of the preceding year that we find in other birds. The writer has noticed that the greater number of cuckoos, which he has examined in spring, were birds of the preceding season, these always having a remnant of the immature plumage upon the wings, two or three of the quill-feathers, and of the greater coverts impending over them, not having been shed; but it is possible that these are more frequently shot, from their being less suspicious and vigilant than the old birds.

We do not think it very probable that, as some persons have imagined, the cuckoo's egg is ever suffered to perish, from the bird not having been success-

ful in finding a suitable nest in which to place it. Judging from past experience in the way of birds' nesting, we should think this almost impossible, more especially as the cuckoo's season for laying is when birds' nests are found in greatest abundance; and penetrating as she does into the very midst of thickets and furze-brakes, we may fairly give the cuckoo credit for being a much better hand at finding them than we are. Although the writer of this has never actually known an instance of the cuckoo's egg being ejected, he has no doubt whatever of this being the sole cause of its extreme scarcity.

A very favourite resting-place of this species is upon an isolated tree, which commands a wide prospect around; and, in such situations, the female cuckoo, concealed amid the thickest foliage she can find, sits quietly and observes the operations of the numerous smaller birds around her; more particularly noticing those which are carrying about building materials, and marking the place of deposit; this, also, is probably another reason why the cuckoo's egg should most frequently be found in the nests of ground building birds.—“A pair of wagtails,” says Mr. Hoy, “fixed their nest, early in April, among the ivy which covers one side of my house, and reared and took off their young. A few days after the young birds had left the nest, I observed the old birds apparently collecting materials for building, and was much amused at seeing the young running after the parent birds, with imploring looks and gestures, demanding food; but the old birds, with roots or pieces of grass in their bills, seemed quite heedless of them, and intent on their new habitation. Their motions were narrowly watched by a female cuckoo, which I saw constantly near the place; but the wagtails had placed their second nest within a yard of the door, and so well concealed among some luxuriant ivy, that the cuckoo, being often frightened away, was not able to discover the nest. The intruder being thus thwarted in its design, the birds hatched their second brood, which was accidentally destroyed a few days after. In about ten days they actually commenced a third nest within a few feet of the situation of the second, in safety. I have repeatedly taken the cuckoo's eggs from the wagtail's nest; in this locality, it has a decided preference to it. I do not recollect finding it in any other, excepting in two instances, once in the hedge-chanter's and another time in the redstart's nest. In this vicinity, whether the wagtail selects the hole of a pollard tree, a cleft in the wall, or a projecting ledge under a bridge, it does not often escape the prying eye of the cuckoo; as, in all these situations, I have frequently found either egg or young.” Sometimes, however, the cuckoo is obliged to wander about a little to find a nest; the writer of this has noticed one, probably when wanting to lay, to hover slowly along the hedges, penetrating into every thick bush, and examining every likely place to find a bird's nest; upon such occasions the cuckoo, no doubt, deposits its egg in the first nest it can find.

One or two cases have been mentioned, but we think they much require corroboration, of the egg of this species having been found in situations where it could not possibly have been laid; that is to say, in domed nests, and others that were so situate that the cuckoo could not, possibly have crept into the place, but must consequently have introduced its egg either by means of the bill or foot. We are very much in want, however, of a new and well authenticated in-

stance of this; for, in the cases which have been mentioned, it is by no means impossible that the egg had been surreptitiously introduced; many school-boys, indeed, would be greatly delighted to think that they had so puzzled a philosopher. In all the instances which have fallen under the observation of the writer, and in all that he has ever heard of, from direct observers (which together amount to a very considerable number), the nest was without exception so situate that the cuckoo could have laid its egg into it.

Mr. Hoy relates the following fact: “I once observed a cuckoo enter a wagtail's nest, which I had noticed before to contain one egg; in a few minutes the cuckoo crept from the hole and was flying away with something in its beak, which proved to be the egg of the wag-tail, which it dropped on my firing a gun at it. On examining the nest, the cuckoo had only made an exchange, leaving its own egg for the one taken.” It invariably, when undisturbed, destroys whatever other eggs there may be in the nest into which it deposits its own, though this fact has not been noticed by writers on the subject. Whatever other eggs, therefore, may be found in the same nest with that of the cuckoo, were not laid, in most instances, till after its deposition. Of this the writer has the most abundant and satisfactory evidence; he has repeatedly known the cuckoo's egg to have been found alone in different nests, and he has been informed by a direct observer, of the following fact: a meadow pipit's nest was found with four eggs in it, which, on being looked at a day or two afterwards, was observed to contain a solitary cuckoo's egg, all the others having disappeared. On searching about the place the broken shells of them were, however, found at a short distance. Another instance was made known to him by a birds'-nesting-boy, of whom he purchased the cuckoo's egg. This lad found a meadow pipit's nest with two eggs in it, and going the next day to look at it, these had both disappeared, and that of a cuckoo was in their place alone; the following day the pipit laid an egg to this, and the day after that another, when the nest was taken from the place. A further proof of this fact may be deduced from the circumstance, that whenever eggs are found in the same nest with that of the cuckoo, they are almost invariably below their average number.

In certain cases which would appear to militate against the above, as in that mentioned by Montagu, in which “the hedge-chanter had four eggs when the cuckoo dropped in a fifth,” it is highly probable that the cuckoo had been disturbed, perhaps by the rightful owners of the nest, before she had had time to finish her operations. The writer of this has seen a meadow pipit attack most resolutely, and drive away, a cuckoo from the vicinity of its abode; he may pretty safely say from off its nest, as the cuckoo rose from the ground. It would appear, indeed, from the last mentioned fact stated by Mr. Hoy, as well as from some other cases that could be adduced, that the cuckoo invariably lays her own egg *previously* to destroying the others. It would otherwise seem rather difficult to account for another fact, that of two cuckoo's eggs being sometimes found in the same nest; of which three or four instances are upon record. “In May, 1829,” says Mr. Hoy, “I found two cuckoo's eggs in the same nest, and depended on witnessing a desperate struggle between the parties, but my hopes were frustrated by some person destroying

it." A similar instance has been related to the writer of this article, but which also met with a like fate. It is most probable that, in these cases, the eggs were laid by two different cuckoos; and the occurrence of this fact seems to show, that the cuckoo, in a hurry perhaps to ease herself of the burden as soon as possible, and fearful also of being caught upon the nest by its rightful owner, hardly looks at or notices the eggs of her dupe before laying her own, and that, afterwards, being unable to distinguish between her own egg and that of another cuckoo, she destroys neither.

The writer of this is unable to say positively, whether the European cuckoo ever devours the eggs of other birds, but he thinks it most probable that it does so; that the cuckoo sucks birds' eggs is everywhere a very common opinion throughout the country, but the mere fact of her destroying them would be sufficient to give rise to this opinion. A female specimen, however, in the writer's possession, has its plumage soiled in several places with yolk of egg, and, though little can be deduced from this circumstance, he thinks it worth while to mention it. It is quite certain that many exotic species, nearly allied to our cuckoo, do feed very much upon birds' eggs. Wilson says of the *Coccyzus Carolinensis*, that "they are accused; and with some justice, of sucking the eggs of other birds, like the crow, the blue-jay, and other pillagers;" and this is further confirmed by Audubon, who says, of the same species, that "the yellow-billed cuckoo of America robs smaller birds of their eggs, which it sucks on all occasions," &c. It is, therefore, more than probable, to judge from analogy, that the European cuckoo does the same.

Having now pretty copiously disposed of all that concerns the cuckoo's egg, we have next to detail the singular and wonderful instinct of the young cuckoo. We have seen that, in the American cattle-bird (see *Cow-Bunting*), nature has provided for the exclusive maintenance of the young stranger, by decreeing that the alien egg should invariably be hatched before the others with which it had been placed; but the young cuckoo bring always a much stronger bird than its fellow-nestlings (when it has any), is endowed with the extraordinary instinct of ejecting them from the nest. This interesting fact was first made known to the world by the excellent Dr. Jenner, "who," as Wilson observes, "has since risen to immortal celebrity in a much nobler pursuit, and to whose genius and humanity the whole human race are under everlasting obligations." To this gentleman are we indebted for the discovery of some of the most interesting phenomena of the cuckoo's history; and honourable mention of his name should be made by every writer who has occasion to treat upon this bird. Speaking of the cuckoo's egg in the nest of the meadow pipit, Mr. Selby observes, "As the same period of incubation is common to both birds, the eggs are hatched nearly together, which no sooner takes place, than the young cuckoo proceeds instinctively to eject its young companions and any remaining eggs from the nest. To effect this object it contrives to work itself under its burden (the back, at this early age, being provided with a peculiar depression between the shoulders), and shuffling backwards to the edge of the nest, by a jerk rids itself of the incumbance; and the operation is repeated, till the whole being thrown over, it remains sole possessor. This particular tendency prevails for about twelve days, after which the hollow space

between the shoulders is filled up; and when prevented from accomplishing its purpose till the expiration of that time, as if conscious of inability, it suffers its companion to remain unmolested." This latter curious fact was first discovered by Colonel Montagu, who (as has often since been done from curiosity), when bringing up a young cuckoo by hand, placed frequently another young bird in the nest with it, for the purpose of seeing it ejected by the cuckoo, and noticing the manner in which this is done. "Sometimes indeed," says he, "it failed, after much struggling, by reason of the strength of the young swallow, which was nearly full feathered; but, after a small respite from the seeming fatigue, it renewed its efforts, and seemed continually restless till it succeeded. At the end of the fifth day" (it had been five or six days hatched when taken) "this disposition ceased, and it suffered the swallow to remain in the nest unmolested."

A nest, however, upon the ground may sometimes be so situate, as to render it impossible for the young cuckoo to turn out its fellow nestlings, of which the writer of this has been told an instance wherein four callow wagtails were found dead, apparently starved, beneath the usurper of their abode.

The young cuckoo's plumage is exceedingly unlike that of the adult bird; so much so, that some of the cabinet naturalists have even described it as a distinct species, under the names of *Cuculus rufus* and *Cuculus hepaticus*. The whole upper parts are generally of a deep clove brown, tinged here and there with grey, and barred with rufous brown, sometimes also margined with whitish. There are usually three spots of white upon the back of the head, but these are sometimes wanting in the young females. The oval spots on the inner webs of the quills are reddish brown. Throat and under parts yellowish white, with transverse black bars; paler upon the belly, a line of demarcation being visible, where in the adult bird the grey ceases upon the breast. Irides, at first greyish, afterwards liver brown, and beginning to change to yellow about the time they leave us in September. Legs and toes primrose yellow. The whole plumage indeed having a pretty transversely barred appearance, which renders them handsomer than the adult birds.

Unlike every other British bird, except the swift and chimney swallow, they leave the country in this their nestling plumage; but do not, as has been suggested, gradually change, without moulting, to the adult colour; they moult about the middle of winter, but as they carry such an immense proportion of feather, the change occupies a longer period than that of most other birds, the young cuckoos having generally some traces of the immature plumage upon the wings when they reappear in spring. As the old females have always some transverse rufous bars upon the sides of the neck and breast, it is probable that these must have given rise to the supposition that the young cuckoos do not moult during their absence, but undergo, like the ptarmigan, a gradual change of colour.

Varieties of this species sometimes occur, as in most other birds, that is to say, variations of colour. The writer has seen a young albino individual, and also a very singular adult one, which was shot in spring, whilst it was repeating its cry. This bird has all the upper parts and breast of a bright rufous colour, beautifully barred with black; not at all resembling, however, the plumage of the immature cuckoo, but more that of the female kestrel hawk; although un-

questionably a mere variety of the common species, this interesting specimen much resembles a newly discovered smaller cuckoo from the Himalaya.

Like the raven and other birds in which the egg is disproportionately small, the young cuckoo grows very rapidly in the nest, and its diminutive foster parents are obliged to labour hard and perseveringly to satisfy its increasing voracity; it requires even to be tended for a longer period than any other bird with which we are acquainted, remaining five or six weeks in the nest; and even long after it has flown, its assiduous nurses may be seen to follow it with food; and in confinement it will very rarely feed of itself till it is two or three months old; at all times indeed, even when able to pick up its own food, preferring to be fed by those to whom it is accustomed. In a wild state, the young cuckoo that has begun to fly, however it may seek to hide itself, may generally be traced by a concourse of numerous small birds chattering around it, among which the swallow kind are mostly very conspicuous, seemingly endeavouring, to the utmost of their power, to annoy it; amidst all which turmoil the pair that have brought it up continue constantly to bring it caterpillars and other insects. A writer observes of one, in the Magazine of Natural History, that "it was seen again on June 12th, on the top of a wall near to the nest; and, while it was sitting here, an amusing and instructive sight presented itself. A thrush, which probably had a nest close by, in an adjoining garden, evinced the most passionate and marked antipathy toward the young cuckoo, by approaching it with feathers ruffled, beak open, and uttering an earnest cry; some small birds too drew near, as if to exhibit their dislike, and abet the thrush. This is indeed quite an ordinary fact; small birds seem to consider the young cuckoo as an enemy, and they persecute it with the same unremitting hostility, and chatter round it with the same unwearied pertinacity which they exhibit toward a weasel or an owl. This is the more singular, as these very birds may, in their turn, themselves become the nurses of a young cuckoo. The same animosity is shown by the different swallows towards the old bird, which they frequently attack and buffet as it flies along.

The cuckoo's food consists principally of insects, chiefly however the larger caterpillars, whether smooth or hairy; these it first kills, by shaking and knocking them violently against the bough on which it is perched, and then renders them perfectly pliant by passing them several times through the bill, before it swallows them. In confinement it seems very fond of the common house-fly, which it will readily take from the hand of a person it is accustomed to. It also feeds largely in spring upon the common may chaffer (*Melolontha vulgaris*), and has been seen to capture dragon flies on the wing. As the summer advances it will attack various kinds of fruit, as cherries and currants. Most probably also, as has already been mentioned, it devours birds' eggs; but caterpillars are its principal and main food, the exuvæ of which it casts up in the manner of a hawk, in pellets, about the size of a sparrow's egg. It is in search of these that the cuckoo is so often seen about fruit trees, to which it doubtless renders an efficient service, as it not only preys upon those which have grown to some size, but also, in the spring, may be frequently seen deliberately picking out the newly hatched larvæ from their webs; an operation which

has strangely enough been construed by many gardeners and others into "sucking the blossoms," if any meaning can be attached to this phrase.

Whilst feeding upon a tree, the cuckoo leans very forward upon the bough on which it is sitting, as it examines the foliage for caterpillars, its tail being generally raised; and it frequently takes very considerable leaps from bough to bough, considering the shortness of its legs. The writer of this has never seen it climb in any sort of way, nor walk up a branch, using its feet alternately; but conceives that the only use of its having two toes on each foot placed backward, is to enable it more firmly to grasp its perch whilst leaning so very forward.

"The tree cuckoos," observes Sir W. Jardine, "though often found near woods, and in richly clothed countries, are fond of open and extensive heaths or commons, studded or fringed with brush and forest: here they may expect an abundant supply of the foster parent to their young. Their gliding and turning motion, when flying in a thicket, is similar to that of the American *Coccyzus*. Like them, also, they are seldom on the ground; but when obliged to be near it, alight on some hillock or twig, where they will continue for a considerable time, swinging round their body in a rather ludicrous manner, with lowered wings and expanded tail, and uttering a rather low monotonous sound, resembling the *kowee* of the American bird—

"Turning round and round with cutty-coo."

"When suddenly surprised or disturbed from their roost at night, they utter a short tremulous whistle, three or four times repeated; and it is only on their first arrival, during the early part of incubation, when in search of a mate, that their well-known and welcome note is heard: by the first of July all is silent." It is not, however, very often that an opportunity occurs of studying this bird's habits so very minutely; all are acquainted with its note, and there are few persons residing in the country, but must have often observed it, as, somewhat in the manner of a pigeon, but less steadily, it wings its way from tree to tree; but the bird is so vigilant and shy, that very few even of those who try to study its habits, can ever get to notice it more particularly, excepting, perhaps, by mere accident, once or twice only in their lives.

When first taken from the nest, the young cuckoo is extremely savage and voracious, buffeting and sparing with its wings like a gamecock, and uttering all the time a shrill cry. They are easily enough reared upon raw meat, but are difficult to keep through the winter, being very tender about the moulting period, which usually takes place about January. In the course of a little time, they mostly become tolerably attached to those they know, but are generally very shy before strangers. Buffon, indeed, says, "though cunning and solitary, the cuckoo may be given some sort of education. Several persons of my acquaintance have reared and tamed them. They feed them on minced meat, either dressed or raw, insects, eggs, soaked bread, and fruit. One of these tamed cuckoos knew its master, came at his call, followed him to the chase, perched on his gun, and if it found a cherry tree in its way it would fly to it, and not return till it had eaten plentifully; sometimes it would not return to its master for a whole day, but followed him at a distance, flying from tree to tree." The writer of this article has seen a pair that were

tolerably tame, that were allowed the free range of a large kitchen, where they commonly used to sit upon the fender, warming themselves by the fire. They are apt in confinement to suffer very much from excess of the migratory feeling, which not unfrequently causes the death of those that are prevented from following this natural impulse.

Upon the whole this species exhibits, when in a state of confinement, a greater degree of attachment to its feeder than we should be prepared to expect. Its brain, we may remark, is very small, scarcely weighing twenty grains, which only exceeds the weight of one of its eyes by a grain and a half.

The old cuckoos are always the very first of our summer migrants to leave the country, as the majority of them retire southward in the first week in July. Woodmen and others say that they congregate, before taking their departure, in flocks of twenty or thirty; and the writer of this is likewise informed, upon very good authority, of a flock of sixteen young ones being seen, in September, in the north of Scotland, flying in a south-easterly direction towards the German ocean, which, at the place of observation, was distant about half a mile. It is probably only in the less populous districts that this can ever be observed. Where the mass of them spend the winter has never been specifically ascertained, though specimens have been received from Egypt.

"Naturalists," says Mr. Selby, "have been puzzled to account for this bird not performing the office of incubation, but as their researches have principally been directed to the anatomical structure, in which point it does not essentially differ from many others that perform this office, we arrive by these means at nothing satisfactory. The above peculiarity of this remarkable genus must not probably be looked for in any principle of conformation, but must be explained from their habits and economy.

"Let it be remembered these birds are migratory, and that the period during which the adults remain with us is very short; but the propagation of the species must be effected during that period. Now, as their arrival does not take place before the month of April, and the egg is seldom ready for incubation before the middle of May, there would not be a sufficient length of time for the young to be hatched, or (making every allowance) sufficiently fledged to accompany the old birds at the period of their departure, which seldom or never extends," in the north of England, "beyond the first week in July."

This perhaps is about as good an explanation of the cuckoo's peculiarities as has hitherto been offered, but it fails, like all the rest, in being quite inapplicable to the case of the North American cow-bunting. The true cause (whatever that may be) of this extraordinary deviation must, we are persuaded, be the same in both; nor can we at present consider any explanation as satisfactory that will not alike apply to either. That the old cuckoos, however, should retire southward in the very hottest part of the summer is certainly a very curious matter, and the cause of this requires further investigation. It cannot be for want of food, for they are then always in prime condition; and caterpillars, their main subsistence, are then much more abundant than when they arrive in spring. No observations, however, have as yet been made upon the cuckoo in its winter quarters, and till this has been done it is of little use attempting to theorise upon the subject. The natural history of

this remarkable bird still offers a wide field for investigation, and it will probably be a long time yet before our knowledge of it can be any thing like complete. It is, without exception, the most extraordinary bird that occurs on the European continent, and as such it merits peculiar and close attention from all who take an interest in natural history. Observations upon it must be multiplied, both at home and abroad, and a great deal must yet be elicited, before a variety of points can be cleared up on which at present we have little more than conjecture.

Of the genus *Cuculus*, a considerable number of species are enumerated, inhabiting different parts of the eastern continent, but chiefly Africa, and varying in size from double that of our bird to less than half. We know, however, very little of their habits, and nothing but what is in entire accordance with those of the species which inhabits Europe. Like it, they are all understood to deposit their eggs in the nests of other birds, but the fact, we believe, has not been ascertained in more than one or two, and even in these rests as yet on the authority of a single observer. Instead, therefore, of entering here into a long detail of colours and proportions, which are very little interesting to the general reader, we will pass on at once to give a brief account of their American representatives, the members of the genus *Coccyzus*, which, with one or two exceptions in Africa, are all confined to the western division of the globe; and we do this the rather, as our account of the European cuckoo has been extended to a very considerable length.

The *Coccyzi*, as a group, are mostly rather smaller than the true cuckoos, which in their general appearance they much resemble. The bill is, however, rather larger in proportion, and the tarsi longer, and bare of feathers. Their plumage is generally rufous on the upper parts, white beneath, and more or less marked, with white upon the tail; and, unlike the cuckoos, the young much resemble the adults. They are rather more confined to the interior of woods than the true cuckoos, and they build their own nests, and rear their young. Several beautiful species are found in South America, and two in the northern division of that continent, one of which has been already mentioned as an occasional straggler to the British islands. This bird, the *Coccyzus Carolinensis*, is thirteen inches long, and sixteen in extent of wing, the whole upper parts are of a dark glossy drab, or what is commonly called a quaker colour, with greenish silky reflections; inner vanes of the wings bright reddish cinnamon. Tail long, composed of twelve feathers, the two middle ones being the same colour as the back, the others, which gradually shorten to the exterior ones, are black, largely tipped with white; the two outer ones scarcely half the length of the middle ones. All the under parts pure white, the feathers covering the thighs (tibiae) being long, as in the hawk tribe. Legs and feet light blue. Bill dusky black above, and yellow below. Irides hazel, with the eyelids bright yellow. The female much resembles the other sex, but has four of the middle tail feathers like the back, and her white is not quite so pure.

"A stranger," says Wilson, "who visits the United States for the purpose of examining their natural productions, and passes through our woods in the month of May or June, will sometimes hear, as he traverses the borders of deep, retired, high timbered hollows, an uncouth guttural sound or note, resembling the syllables kowe, kowe, kowe-kowe-kowe, beginning

slowly, but ending so rapidly that the notes seem to run into each other, and vice versa; he will hear this frequently without being able to discover the bird or animal from which it proceeds, as it is both shy and solitary, seeking always the thickest foliage for concealment; a trait in its character, by the way, closely reminding us of the European cuckoo. "This," continues Wilson, "is the yellow billed cuckoo (*Coccyzus*), the subject of the present account. From the imitative sound of its note, it is known in many parts by the name of the *Cow-bird*; it is also called in Virginia the *Rain-crow*, being observed to be most clamorous immediately before rain.

"This species arrives in Pennsylvania from the south about the 22nd of April, and spreads over the country, as far at least as Lake Ontario; it is numerous in the Chickasaw and Choctaw nations, and also breeds in the upper parts of Georgia; preferring in all these places the borders of solitary swamps and apple orchards. It leaves us, on its return southward, about the middle of September." Mr. Audubon adds, that "in their migrations northward they move singly, but when removing again to a warmer latitude they appear to be gregarious, flying high in the air, and in loose flocks." This tends analogically to confirm what we have already advanced concerning the European cuckoo's migration. That species seems also to arrive singly, and to depart southward in small flocks.

"Early in May," says Wilson, "they begin to pair, when obstinate battles take place among the males. About the 10th of that month they commence building. The nest is usually fixed among the horizontal branches of an apple tree; sometimes in a solitary thorn, crab, or cedar, in some retired part of the woods. It is constructed with little art, and scarcely any concavity, of small sticks and twigs, intermixed with green weeds, and blossoms of the common maple. On this almost flat bed the eggs, usually three or four in number, are placed; these are of a uniform greenish blue colour, and of a size proportionable to that of the bird. While the female is sitting the male is generally not far distant, and gives the alarm, by his notes, when any person is approaching. The female sits so close that you may almost reach her with your hand, and then precipitates herself to the ground, feigning lameness, to draw you away from the spot, fluttering, trailing her wings, and tumbling over, in the manner of the partridge, woodcock, and many other species." We cannot but contrast this affectionate display of parental feeling with the conduct of the European cuckoo. Some writers, however, as Dr. Darwin and others, even state of that species, that it sometimes builds a nest and rears its own progeny; but the instances they mention clearly show that they had mistaken a very different bird, the nightjar, for a cuckoo; the accounts which they furnish accord entirely with the nidification of that species, which indeed in the nest bears no inconsiderable resemblance to it; and the writer of this has himself known an instance of a young nightjar being mistaken for a cuckoo. Still it would be interesting, before we entirely divest the European cuckoo of all parental affection, to try whether an old caged one would take any notice of a nestling of its own species that was placed along with it; to see whether it would be moved, like other birds, by its helpless cries, and ever place food into its mouth. We should imagine, however, that it would not.

"Both parents," continues Wilson, "of the Carolina *Coccyzus* unite in providing food for the young. This consists, for the most part, of caterpillars, particularly such as infest apple trees." The same insects constitute the chief part of their own sustenance. They are accused, and with some justice, of sucking the eggs of other birds, like the crow, the blue jay, and other pillagers. They also occasionally eat various kinds of berries. But, from the circumstance of destroying such numbers of very noxious larvæ, they prove themselves the friends of the farmer, and are highly deserving of his protection.

"In examining this bird by dissection, the inner membrane of the gizzard, which in many other species is so hard and muscular, in this is extremely lax and soft, capable of great distension; and, what is remarkable, is covered with a growth of fine down or hair, of a light fawn colour. It is difficult to ascertain the particular purpose which nature intends by this excrescence; perhaps it may serve to shield the tender parts from the irritating effects produced by the hairs of certain caterpillars; some of which are said to be almost equal to the sting of a nettle." The same has also been said, first probably by some compiler who had read Wilson's article and who thought he might safely enough infer it from analogy, of the stomach of the European cuckoo, but the writer of this has dissected several, and never observed any thing of the kind. The cuckoo's stomach is, however, lax and membranous, like that of the American bird.

Black billed *Coccyzus* (*C. erythrophthalmus*). "This species," according to Wilson, "is nearly as numerous as the former, its peculiar markings, however, and some of its habits, sufficiently characterise it as a distinct species." Its general colour above is nearly that of the former, inclining more to a pale ash on the cheeks and front; it is about an inch less in length; the tail is of a uniform dark silky drab, except at the tip, where each feather is marked with a spot of white, bordered with a slight touch of dull black; the bill is wholly black, and much smaller than that of the preceding, and it wants the bright cinnamon on the wings. But what constitutes its most distinguishing trait is a bare wrinkled skin of a deep red colour, that surrounds the eye, whence the species have, though not very accurately, been named *erythrophthalmus*, or red-eyed.

"The black-billed *Coccyzus* is particularly fond of the sides of creeks, feeding on small shell-fish, snails, &c." I have also found broken pieces of oyster-shell in its gizzard, which, like that of the other, is covered with fine downy hair. Audubon found in the stomach of this bird, in addition to shells and water insects, "a small black frog, which appears after a summer shower." The sustenance, therefore, of this species is rather anomalous, and peculiar for a member of the cuckoo family.

"Its nest is commonly built in a cedar, much in the same manner and of nearly the same materials as that of the other; but the eggs are smaller, usually four or five in number, and of a rather deeper greenish blue."

There is nothing known of the peculiar habits of the other species of this division, so it would be here little interesting to detail their colours and proportions. A notice of other birds allied to the cuckoo will be found in the articles *LEPTOSOMUS*, *INDICATOR*, and *PHENICOPTERUS*.

CUCKOO FLOWER is the *Lychnis flosculi* of Linnaeus, a common British plant found in moist meadows. It belongs to the tenth class and fifth order of the sexual system, and to the natural order *Caryophyllææ*. The *Cardamine pratensis*, another common plant in moist meadows, is also called cuckoo flower, but the plants are in no way connected except in habitat.

CUCULIDÆ (Stephens; PLATYSOMA, Latreille). A family of coleopterous insects of small extent and lignivorous habits, placed between the *Xylophaga* and the *Longicornes*, having the tarsal joints entire and not bilobed; the antennæ are of an equal thickness, or slender at the tips; in some species, however, the three terminal joints are incrassated; the jaws are robust and exerted, and the body very much depressed and of an oblong form. These insects are of small size, and are found beneath the bark of trees, where also the larvæ reside. Their situation appears to be much nearer to some of the *Necrophagous Pentamera*, such as *Ips*, than to the *Longicorn Tetramera*. The genera are *Cucujus*, *Dendrophagus* and *Uleiota*, to which Mr. Stephens has added that of *Trogosita* of Fabricius. The typical genus has the antennæ shorter than the body, with the basal joint shorter than the head. There are several British species, but their synonymy is very confused. The males of *Uleiota flavipes* have the mandibles armed with a remarkable curved horn.

CUCULINÆ (Latreille). A subdivision of the insects composing the family *Apidæ*, or true long-tongued bees, distinguished by the non-possession of organs for the gathering of pollen, and consequently compelled to resort to the nests of other bees for the deposition of their eggs. Hence, like the cuckoo, they may be regarded as a kind of parasite. The larvæ of all bees are nourished by a paste formed of pollen and honey, but in nearly one-third of the genera of these insects the females are destitute both of pollen brushes and pollen plates. Having, therefore, with much artifice succeeded in introducing its eggs in the already provisioned nests of other working bees, the female cuckoo bee is enabled, without the toil of constructing a nest, to ensure for its progeny as much benefit as though it had been especially provided for, since the parasite larva is supposed to hatch before the larva which is the true inhabitant of the cell, and of course it immediately devours the supply of pollen paste, so that when the real inhabitant is hatched, its food being consumed, it is of course starved to death. But this parasitic kind of connection exists in other groups besides those included by Latreille in the family *Cuculina*: thus some of the humble bees\* (*Bombus*) are in like manner destitute of polliniferous organs, and compose the genus *Psithyrus* of St. Fargeau (*Apathus*, Newman; *Pseudobombus*, Stephens); whilst other genera, not only amongst the *Apidæ*, but also in the *Andrenidæ* (short tongued bees), and even in the *Fossorial hymenoptera*, are similarly circumstanced. As, however, the structure of these parasite bees (except as regards their polliniferous organs) is in many cases too nearly identical with that of the bees, in the nests of which they are parasitic (compare *Bombus* and *Psithyrus*, which Mr. Curtis thinks should not be even gene-

rically separated), we do not feel inclined to adopt the step taken by Mr. Newman of uniting them all, whether *Apidæ* or *Andrenidæ*, together under the name of *Apathites*, although, for convenience' sake, we have followed the steps of Latreille in keeping the *Cuculina* as a distinct group. See *APIDÆ*. The genera introduced by Latreille into this subdivision are, *Ammobates*, *Philceremus*, *Epclus*, *Nomada*, *Psites*, *Melecta*, *Crocisa*, and *Oxæa*.

CUCULLÆA (Lamarck; *ARCA CUCULLUS*, Linnaeus). This genus nearly resembles the Linnæan *Arks*, from which modern naturalists have generally separated it. De Blainville, however, in this instance as in many others, with a view to conform as closely as possible to the system established by that illustrious naturalist, and not to multiply genera uselessly, has made it a subdivision of the genus *Arca*; in this we do not coincide altogether, as there are some manifest distinctions of structure which indicate a different inhabitant. The shape is more gibbous, or trapeziform; the anterior side truncated obliquely, and at the hinge (which in young shells is similar to that of the *Arks*), by growth or age, becomes displaced, or appears obsolete, exhibiting parallel ribs, which terminate it and give the teeth a more horizontal appearance than in the *Arks*, as they are now defined by Lamarck. But the most remarkable distinction, and one from whence its name of *hooded* has been derived, are the ear-shaped testaceous appendages, placed internally at an angle with the anterior surface, on one side of the muscular impression of the valves; these form a species of chamber or division, and are not to be found so situated in any other species of mollusc. The shell is equivalve, inequilateral, rhomboidal, heart-shaped, truncated at one end, and very globose; the umbones distant and separated by the angular groove or area of the ligament, which is altogether external; the hinge linear, straight, with small transverse teeth, having at its extremity from two to five parallel ribs. Lamarck does not mention that the valves are marked with minute and strong longitudinal striæ, one valve often overlapping the opposite one, and that the margins of them are crenulated. From this difference in the size of the valves, many collectors have supposed examples with the ligament broken, not true pairs; but it is a character peculiar to this genus, and also to some of the *Arks*, though not constantly observable in either. It is a circumstance rarely occurring in other bivalves, and one only to be accounted for hypothetically, by supposing the animal to complete the enlargement of his dwelling on one side first, and not on both simultaneously; and this is rendered the more probable, as it is found not to be a constant characteristic. It closely allies this genus with them, and is a proof of the truth exhibited, and the necessity of combining a knowledge of the animal with the distinctions furnished by its dwelling, in order to constitute a correct system of classification. This is the science of malacology.

CUCULLIA (Schrank). A genus of lepidopterous insects belonging to the section *Nocturna*, and family *Noctuidæ*, having the upper wings long and lancet shaped, acute at the tips, the abdomen elongated, and the spiral tongue as long as the antennæ. These moths are called sharks by the English collectors. The generic name is given to them in allusion to the hooded thorax. The species are very difficult to discriminate, from their great resemblance in the pre-

\* For an account of the genus *Bombus*, or the humble bees, see HUMBLE BEE.

† The quotation from Mr. Selby, given in p. 195, relating to the cuckoo, may, to a certain extent, be applied with equal force to these cuckoo bees.

fect state, the caterpillars affording the best characters for specific differences in the genus. The moths fly very strongly. Reaumur has given us an account of the proceedings of the larvæ of one of these moths (*C. scrophulariæ*), in the construction of its cocoon, which is formed of particles of earth fastened together. Having dug up one of these caterpillars which had just completed its case, he broke off one end, in order to see the manner in which the insect would repair the damage. After thrusting out its body almost to its full extent, and reconnoitering the adjacent ground, it selected a grain of earth and fastened it into the breach with a thread of silk; proceeding in this way, it almost closed the hole, the outside being built of larger grains, and the interior of finer. Moreover, previous to completely closing the aperture, it gathered a quantity of earth on the inside, which it thrust with its head into a silken network woven over the part which still remained open, by which means the whole was rendered opaque and equally firm with the unbroken part. There are about a dozen British species, including the typical species above mentioned, which is one inch and three quarters in expanse. The larva is found upon the water betony. The larvæ of all the species are handsome caterpillars, and the chrysalides have the head-case produced.

CUCUMBER, is the *Cucumis sativa* of Linnæus, and a well-known horticultural plant, extensively cultivated for its green fruit.

Of the cucumber, it may be averred, that there is no plant in cultivation which receives more care and attention from the kitchen-gardener than this. The earlier the fruit can be had in the season, the more they are prized. Fruit in general are most valuable when mature; the cucumber, on the contrary, is only useful when very young and green; indeed, the younger the fruit, when large enough for table, the more it is esteemed.

A fine cucumber brought to table on Christmas day, and which has been cut from a plant raised from seed sowed after the 20th of October preceding, is certainly the most costly fruit ever seen on the tables of the rich. For estimating the time, labour, and materials employed in the production of such a luxury, the expense is certainly greater than is bestowed on any other vegetable delicacy. It is true, a gardener is not kept entirely for the purpose of growing early cucumbers, this being only a part of his other more material duties; but, calculating the attention and time dedicated to this sole object, the labour greatly exceeds the worth of the production. However, as it is one of those gratifications expected from the possession of an expensively kept kitchen garden, it should always make a part of the superintendent's duty.

As an exotic, and the production of a warm climate, it requires an artificial temperature in this country, more especially when cultivated during our coldest season. This can only be afforded by fire-heat, or that of some fermentable substance. The most common, because the most plentiful material for the purpose, is stable litter, after being thrown to the dunghill, which being properly prepared by frequent turning, to allow the rank ammonious steam to evaporate, is made into beds, covered with frames and glazed sashes, and with suitable compost to receive the plants.

There are various ways of forming the beds; some are formed entirely of prepared dung, raised four feet or more in height, on which the frame and

lights are set. However high this hotbed may be raised, its heat will decline at last, and often, at the very time a lively bottom heat is most wanted; in this case, linings of hot dung are applied to renew the heat, and which require to be often repeated. The greatest objections to this kind of hotbed are—the heat is too strong at first, and when it declines, sufficient heat cannot be imparted to the middle of the bed by linings. From the first the plants are liable to be burnt; and from the second, chilled. To avoid these extremes, some gardeners make a new dungbed, of moderate depth, on the top of an old one, and trust entirely to linings for bringing the plants to perfection. By this plan, there is no fear of burning the roots; and when the linings are timely applied, this method succeeds very well. Others dig pits for hotbeds, having the sides and ends of open, or pigeon-hole brick-work, leaving a vacuity two feet wide all round, for the reception of linings, on which the cultivator chiefly depends for a sufficient and equable degree of heat. In this mode, it is usual to fill the pit within the walls with brick-bats, or brushwood, half way up, on which the prepared dung and compost are laid, to receive the plants. By these means the heat from the linings is collected in the hollow brushwood-filled space, whence it rises in a constant and moderated stream through the dung and mould of the bed, gently exciting and nourishing the plants. Others, again, to be free from the labour of applying linings every ten or twelve days, have a steam, or hot-air chamber, under the bed, whence the requisite heat is derived. In short, there are scores of different schemes for growing early cucumbers, and all are more or less successful, according to the degree of attention or skill bestowed on the culture.

At one time, growing early cucumbers for prizes given at shows, was a favourite amusement among many gardeners round London and some other places. The competitors were bound, by certain rules, as to the time of sowing, viz.—not till after the 20th of October, and the prizes were awarded to the finest and most perfect fruit. Length, regular shape, greenness, regularly garnished with short black prickles, finely covered with a white mealiness, called bloom, and, if still bearing the unfaded blossom on the end, all, or the greatest number of these properties, combined in any one fruit, determined the judges in making their award, and without knowing to whom the fruit belonged till after they had given judgment. It is hardly to be credited with what exactness these punctilios were attended to by the judges, and what pains were taken by the competitors to grow and show fruit answering to the established ideas of a perfect show-cucumber. Glass tubes, and various other modes of confinement, were practiced to give the proper shape. If any prickles were wanting, others, taken from inferior fruit, were ingeniously substituted. If the mealy bloom had disappeared, it was restored by an easy process of puffing hair-powder, or some such floury matter, upon it, in a box made for the purpose; and as it often happened that fine fruit would be ready long before the show-day, the growers had a clever device of keeping them in a fresh unaltered state, by burying them (properly packed) deep in the ground. In fact, the business of growing and showing cucumbers for prizes was a distinct branch of the gardener's occupation, and excelled in but by few.

The ordinary process of raising early cucumbers is executed as follows:—About the beginning of October, a sufficient quantity of fresh stable dung is got together in a convenient open place, where it can be repeatedly turned, watered if too dry, and intimately incorporated, so that no part of the heap shall be wetter or drier than another, but all of equal colour and temperament. On the careful preparation of dung intended for hotbeds, as already observed, much of the success of their purpose depends. If the dung be too wet, the heat rises too violently at first, and is too soon over; and if it has not been turned enough, and all the rank qualities dissipated, the effluvia rising from the bed, after being made, would be highly injurious to the young plants.

Of such prepared dung, a seed-bed for a one light box or frame is made about the 15th of October. By the 20th, the heat will have risen, and its quality judged of, whether an agreeable sweet heat, or having a strong ammoniacal scent; if the latter, it must have time to pass off, or be qualified by a covering of dry leaf-mould or saw-dust. Previous to sowing the seed, pots, or deep pans, filled with a compost of equal parts of fresh loam, leaf-mould, and well rotted dry dung, should be set within the frame to get warm. In this single seeds are dropped two inches apart, and covered half an inch deep. The air within the frame should be kept at about 65° or 70° of Fahrenheit.

It is usual to prefer seeds three or four years old for early forcing, because plants from these show fruit sooner. But some practitioners prefer new, or such as has been saved in the same year, because, say they, the seedlings are more vigorous; and though the plants may require more stopping, they yield at last finer fruit, and nearly as soon as plants raised from old seeds.

In sowing, it is well to place each seed on a nodule of decayed dung, as on this the first fibres take firm hold, and which renders their removal into pots easy and safe, and which transplanting should be done as soon as the seedlings show their first bud of rough leaves. The plants are placed two or three together in each pot, watered, and immediately plunged in the seed-bed. They should be kept within six inches of the glass, receive fresh air daily, and be securely covered on nights by mats fastened to the frame.

While the seedlings are thus being reared in the seed-bed, a fruiting-bed must be prepared for them. The different methods of making these we have already described; and here it only remains to add, that when the fruiting-bed is ready to receive the plants, by having hills of compost laid under each light or sash of the frame, when a due degree of heat has risen through them, and the air within, sweet and of proper temperature, a pot of plants is turned out, and placed on the top of each hill, about six inches from the glass. In doing this, the ball of roots discharged from the pot is kept entire, and the compost pressed closely round, and about an inch in thickness over the top, among the stems. This will induce the production of new roots from the stems, and greatly assist the establishment of the plants in their new abode. If heat from below, moisture in the mould, and air within the frame, be regulated properly, and if water (warm) and fresh air be given cautiously, and every ray of light admitted, with sufficient coverings on nights, the roots will soon extend themselves

through the sides of the hills, in which case additions of compost are from time to time applied, till the whole surface of the bed is covered, and which should be at the general depth of about ten inches.

At this time the season is, perhaps, becoming more and more severe, and therefore the heat must not be allowed to fail, but rather, if possible, increased, and so continued, to swell off the fruit. The temperature of the bed may be lowered or heightened by the thickness of the night coverings, and these must be regulated according to the degree of bottom heat obtained from the means employed, whatever these may be.

A very material part of the management of the cucumber plant depends on the pruning it receives. It is a climbing vegetable; its tendency to grow upwards, and support itself by its tendrils on other plants, must be counteracted in the earliest stage of its growth, by pinching off the extremity of the leading, or principal shoot. This appears like a bud at the base of the first rough leaf on the first joint above, and between the cotyledons or seed-leaves, and soon as it is of the size of a small pea, must be removed. This mutilation induces the production of lateral branches, which readily take a horizontal range, and are allowed to run till they show fruit. But if they produce nothing but male flowers, on the first fourteen inches of their growth, they should be again stopped, to cause the production of a second set of branches, which rarely fail to show fruit abundantly.

As soon as the female flowers are fairly expanded, it is an old custom to impregnate them by hand. In such a situation, where neither bees nor wind can enter, manual assistance appears to be necessary; for, though it is no object whether or not the seeds of such fruit be impregnated, and though it is known that unimpregnated fruit arrive at a certain degree of perfection, it is also well known that a duly fecundified fruit swells faster than one which has had no impact of the pollen at all. This being the case, it is well to follow the old custom, as it certainly can do no harm.

The compost for cucumbers should be rich and porous; rich, because the plant is a "gross feeder;" and perfectly loose, to prevent burning, by giving a free transit to the humid warmth from below. The openness of the compost also admits water readily, and gives free scope to the spreading roots. Leaf-mould, and fresh and turfy loam, which has lain under a heap of good dung for a month or two, and afterwards mixed with twice its bulk of leaf-mould, will be found very suitable.

It has been already observed, that the rank steam of stable-dung is destructive to young cucumber plants, as indeed it is to most others; but after this rankness is gone off, they appear not to be averse to the mild effluvia arising from the body of the bed. On this account it is a good practice, in order that this effluvia may be evolved more copiously, to water and hand-fork up the dung between the hills frequently before the bed is moulded over; and yet, after linings begin to be applied, care must be taken that the warm steam from them does not enter the frame, which it is apt to do, especially if the night-coverings are suffered to project, or hang over the new linings. A further precaution is, to cover the linings with boards or dry earth.

If the attempt to obtain early cucumbers has been

successful, perfect fruit may be had about Christmas, or soon after; but, as it is only adepts in the art of forcing who can insure such a result, few gardeners begin hotbed-forcing before the 1st of January, especially where there are pineries in which cucumbers may be had throughout the winter. But, whenever hotbed-forcing is commenced, the same processes as detailed above are had recourse to, even up to the time they are planted in the open air, except only that the beds are not made so substantial, nor are linings so often required as in winter.

Cucumbers are successfully cultivated in the open air by the assistance of small pits of hot dung and hand-glasses. About the beginning of April, seeds are sown in a hotbed in quantity according to the number of hand-glasses intended to be used. The seedlings, when fit, are potted into forty-eight or thirty-two sized pots, three plants in each. These are kept in the hotbed, stopped, watered, &c., till about the 20th of May, when the pits or ridges should be ready to receive them. A row of pits, each two feet square and fourteen inches deep, are made, the earth being laid round in the form of a ridge lengthways. The pits are two feet apart from each other, and are filled with hot dung prepared for the purpose, firmly beaten in, and raised somewhat higher than the natural surface of the ground. In the centre of the dung, in each pit, direction-sticks are placed, which serve to point out the depth of compost to be laid on, as well as the exact place of the hand-glasses. Round these sticks the compost is laid in a square form, to receive the glasses, which, for the sake of regularity, are set by line. Next day the heat will have warmed the compost; a pot of plants is turned out, and placed in the centre where the direction-sticks stood; water is given, and the glasses put on, and shaded with a mat for a day or two, till the plants have recovered the check of removal. On the third, and every following day, the glasses should be tilted on the south side by a brickbat, and shut close down again on nights, and always also in inclement weather. Three feet of the ground, on each side of the glasses, should be dunged and digged, working the earth towards the glasses in a ridge-like form, on which the branches of the plants are laid when they are laid out from under the glasses. This takes place when the leaves and vines have filled the glasses; the latter are then lifted off, and the former are laid out around, and carefully secured to the ground by small hooks. The glasses are again replaced, but supported by bats all round. This replacing of the glasses is not for the purpose of attracting or keeping in heat, but for defending the dung and stems from immoderate and chilling rain.

This method of growing cucumbers is well imitated by the cottager, who uses green weeds instead of dung, and an old garment instead of a hand-glass.

Cucumbers for pickling may be grown without hot-dung pits, if the plants be raised in a hotbed, and planted out on warm borders about the end of May; or, on the same situation, if the seeds of the short prickly sort be sown on well digged rich ground, a fair yield of picklers may be obtained before the frosts of autumn kill the plants.

There are many varieties of this plant. The favourite kinds for early forcing are the Early Frame, Long Frame, and the Fine Southgate. For ridging out under hand-glasses, there are

The Ridge Cucumber, Early Cluster,

Long Prickly, Green Prickly, Short Prickly, White Turkey, and the White Spined, and the Green Turkey.

**CUCUMIS** (Linnaeus).—A rather extensive and useful genus of creeping or climbing annual plants, natives of many different parts of the warmer regions of the world. Linnaean class and order *Monocotyledon*, and natural order *Cucurbitaceæ*. For descriptions of this genus and its alliances, see *CUCURBITACEÆ*.

**CUCURBITACEÆ**—the gourd family. A natural order of dicotyledonous plants, containing twenty-one known genera, and nearly two hundred species. It is closely allied to *Passifloræ*, differing however from this order in its monopetalous corolla, sinuous stamens, unisexual flowers and exalbuminous seeds. It also bears some affinity to *Myrtaceæ* and *Onagraceæ*. The essential characters of the order are: flowers usually unisexual; sepals five, more or less united, sometimes obsolete; petals five, often more or less united, and sometimes continuous with the calyx, with strongly marked reticulated veins, sometimes fringed; stamens five, distinct or cohering in three bundles; anthers two-celled, very long and sinuous; ovary inferior, one-celled, combined with the calyx; style short; stigma three to five, two-lobed, thick, velvety, or fringed; fruit fleshy, more or less succulent, crowned by the scar of the calyx, one-celled; with three parietal placentas; seeds flat, ovate, enveloped in an arillus, which is either juicy or dry and membranous; testa coriaceous, often thick at the margin; embryo straight, without albumen; cotyledons foliaceous, veined; radicle next the hilum.

The plants belonging to this order are herbs, having annual or perennial, fibrous or tuberous roots, succulent stems climbing by means of lateral tendrils, palmated alternate, rough leaves, and solitary or panicle flowers of a white, red, or yellow colour. They are found in hot climates in both hemispheres, but chiefly within the tropics. They are most abundant in India; a few exist in the northern parts of Europe and America; and some grow at the Cape of Good Hope.

This order is one of the most useful in the vegetable kingdom, containing the various species of gourd, cucumber, and melon, which are well known as articles of food; and furnishing colocynth and elaterium, which are valuable in a medical point of view. In general the properties of the order may be said to be bitter and laxative. These qualities pervade more or less all the species of the order; and according to the degree in which they are exhibited, the plants become esculent or purgative. Some of the gourd tribe contain a resinous principle in which the activity of the plant resides, while in others its place is supplied by milder ingredients, such as mucilage and water. The seeds of cucurbitaceæ are sweet and oily, and are capable of forming an emulsion with water. Their leaves and roots are frequently filled with an acrid, bitter, and drastic juice.

The order has been divided by Decandolle into two sections, *Nandirobiæ* and the true *Cucurbitaceæ*. The former includes the genera *Feuilleu* or *Nandiroba* and *Zanonia*, while the latter comprehends the genera *Cucurbita*, *Cucumis*, *Bryonia*, *Elaterium*, *Momordica*, *Joliffia*, &c.

We shall first notice the genus *Cucumis*, as furnishing a good illustration of the properties of the order.

*Cucumis sativus* is familiar to every one as yielding

the common cucumber. Its original station has not been accurately ascertained. It is the *Ketimon* or *Timon* of the Indians, and is considered by many as a native of Tartary and the East Indies. It was introduced into this country in 1597, and is at present in general cultivation everywhere. There are several varieties of the plant, the most important of which are, the green cucumber, the yellow, the white, the variegated, and the peaked.

The common rough green prickly cucumber produces fruit six or seven inches long, of a dark green colour, and set with small prickles. It bears well, but not early. The short green prickly bears a smoother fruit, three or four inches long. It is one of the hardiest and earliest of the varieties. The long green prickly, the early green cluster, the long smooth green and white Turkey, the large smooth green Roman, and the long white prickly Dutch, are well known to gardeners all over the country.

Cucumber seeds are sown in hotbeds covered with frames and glasses for early fruit, and in the open ground for late crops. The earthy mould, which is spread over the dung of the hotbed, ought to be light and of a rich quality. The glasses should be covered with mats or straw during the night, so as to protect the plants from the cold. A regular supply of heat and a due allowance of moisture are the circumstances which demand attention in their cultivation. There are generally three crops in the year: the first in March and April, from the plants reared altogether in the hotbed; the second in May and June, from those which are raised under hand-glasses; and the third in August and September, from those which have grown on ridges in the open air without artificial heat. The early short and long prickly sorts are preferred for the first crops. In cultivation, those with the smoothest rind and fewest seeds are most esteemed. The cucumber has not the sweet taste and delightful perfume of the melon. When fresh, it is insipid, watery, and even in some degree nauseous. After its outer covering has been taken off, it is cut into thin slices and eaten with vinegar, oil, and pepper. It is not very nutritive, but is greatly relished by many persons. The emperor Tiberius is said to have been very fond of cucumbers, and by proper management he was able to procure one every day at all seasons of the year.

The pulp of the cucumber when fresh is employed as a cooling external application, and a pomade is made from it which is used to soften the skin and remove any slight scaly eruptions which may appear on it. The seeds are made into an emulsion. When in a young state, the cucumber is used for pickles under the name of *Girkins*.

Cucumbers are produced in great quantity in some parts of England. It is stated, that the village of Sandy in Bedfordshire has produced 10,000 bushels of cucumbers fit for pickling in the course of one week.

*Cucumis Melo*, common or musk melon, is a plant highly prized on account of the delicious fruit which it produces. It was originally a native of the western countries of Asia, and is called *Retimon* by the Indians. It has been cultivated in our gardens since the year 1570, and is extensively diffused all over Europe. There are several varieties of the plant, the chief of which are, the netted, the Cantalupe (so called from a place near Rome where it is much cultivated), and the Maltese melon. By cultivation

the varieties of melon have of late been greatly multiplied.

The melon is raised from seeds, and requires the same apparatus and care as is necessary for the cucumber. The frames and pits should be rather deeper, and brick pits are in general preferred. For the early crops the seeds ought to be sown about the middle of January or the beginning of February, and sowings ought to take place again in March, so that a succession of crops may be obtained. After five or six weeks' growth in the first hotbeds, the plants may be transferred to fruiting beds where there is more space and a better supply of air. As the melons approach to maturity, pieces of slate or tile should be placed under each of them in order to prevent them being injured by damp, or acquiring an earthy flavour. Moisture ought not to be supplied in great quantity until the fruit is perfectly set.

The melon, on account of its luscious sweet taste, is valued as a summer fruit, and is commonly produced on our tables as an article of dessert. Its flesh is also preserved in vinegar and sugar. It is much more refreshing than nutritive. In France it is eaten in great quantity both before and during dinner. In that country it is a common addition to boiled beef. It is a fruit by no means well adapted for weak stomachs, inasmuch as it is digested with difficulty. It is apt to produce affections of the bowels and stomach, and as a good precaution ought always to be eaten with pepper or some aromatic stimulant. It is said to be beneficial in some chronic affections of the kidneys, bladder, and chest. The pulp of the fresh melon is sometimes applied with advantage to burns and contusions, and when boiled it forms a good emollient poultice. The seeds contain mucilage and fixed oil, and are known in France by the name of *Semences froides*. They are deprived of their outer covering and triturated with water, so as to form an emulsion, which has been administered in ischuria, inflammations of the kidneys and bladder, and in inflammatory fever.

*Cucumis colocynthis*, colocynth or bitter cucumber, is an annual plant which grows abundantly in Turkey, Nubia, and the Islands of the Archipelago, and is sometimes cultivated in other parts of Europe. The fruit of the plant is a yellow globular berry, the size of a small orange, containing a white spongy substance in which numerous seeds are imbedded. The fruit is much used in medicine, and is imported into this country from the Levant. It is gathered in autumn, when it begins to turn yellow, and having been deprived of its outer coat is dried quickly in a stove or in the sun. By this means the pulp is converted into a white papery looking matter, and in this state is commonly known by the name of *Coloquantida apple*. The white spongy or medullary part of the fruit, deprived of its rind and seeds, is the only portion of the plant which is employed medicinally. It is inodorous, and has an intensely bitter and nauseous taste. Alcohol extracts its bitterness, and acquires at the same time a yellow colour. The alcoholic solution, when evaporated, yields a resinous substance which, from being considered the active principle of the drug, has been denominated *Colocynthine*. It does not, however, appear that the proper purgative principle of colocynth has been discovered.

Colocynth is a drastic purgative, and as such was employed in ancient times by the Greeks and Romans for the cure of dropsies, apoplexy, madness, and

lethargic complaints. On account of its powerful effects, it requires to be administered with great caution. It acts chiefly on the lower part of the intestinal canal, and in large doses is apt to produce violent griping, and even inflammation. It has in some instances proved fatal, by causing severe vomiting and purging.

Colocynth is sometimes prescribed in substance in doses of five or six grains mixed with mucilaginous or farinaceous matter; but it is more commonly administered in the form of extract made into pills. It is sometimes combined with camphor and hyoscyamus, which tend to moderate its griping effects. The watery decoction or infusion is said to be milder than either the powder or extract, but its extreme bitterness prevents its general use. The compound colocynth pills, which are often sold under the name of Dr. Gregory's pills, are composed of the pulp of colocynth, aloes, scammony, oil of cloves, and sulphate of potass.

According to Thunberg, the fruit of the colocynth is rendered so perfectly mild at the Cape of Good Hope, by being properly pickled, that it is eaten both by natives and colonists. The seeds of the plant are bland and nutritious, and constitute an important article of food in northern Africa.

*Cucumis citrullus* formerly *Cucurbita citrullus*, the citrul, is a native of the south of Europe, and grows also in Africa and India. It is called *Lamanka* by the Indians. Two varieties of this plant are mentioned, the *Pasteque* and the *Water melon*. In the former the flesh or pulp is firm, while in the latter it is watery and of a reddish colour.

The water melon is a smooth globular fruit with a green exterior. It is cooling and refreshing, and is frequently produced at table in summer. It is much cultivated in the warm countries of Europe. In Provence the fruit is highly prized, and in India it is in great request during the hot season. In Egypt it is used to quench thirst, and to allay febrile excitement. The seeds are sown at the end of February in hotbeds, and the plants are afterwards removed to fruiting beds, and treated like cucumbers and common melons.

*Cucumis anguria*, round prickly cucumber, is a native of the West Indies, and forms an ingredient in soups. Besides this there are several other species of cucumbers, which are cultivated in a similar manner for domestic use. They are not so important as those already noticed, and it is unnecessary to dwell upon them.

We shall therefore proceed to another genus, *Cucurbita* or gourd, whence the name of the order is derived.

*Cucurbita Pepo* or *Pepo macrocarpus*, the pompon or pumpkin, is originally from India, but is at present cultivated in most parts of Europe. It is one of the plants which acquires in the course of a single season dimensions of no ordinary kind. The stem, which is herbaceous, cylindrical, and hollow, sometimes attains a length of thirty or forty feet, and covers one-eighth of an acre. Its flowers are large, axillary, and of a fine yellow colour. The fruit is red, and acquires sometimes a diameter of two feet. There are two varieties of the plant, one with roundish, the other with oblong fruit. Its flesh is firm and has an agreeable taste; it is refreshing and slightly laxative, but is not used in medicine.

In England the pumpkin is occasionally planted

by country people on dunghills beside their cottages, and the fruit, when ripe, is hollowed out and stuffed with sliced apples, sugar, and spices, so as to form, when baked, what is called pumpkin pie. On the continent, both the unripe and ripe fruit is used in soups, and is fried in oil or butter. The tender tops of this and other species are boiled as greens. The seeds are employed in the same way as those of the cucumber and melon.

*Cucurbita melopepo*, melon pumpkin or squash, is another species of the genus which is cultivated in America as a culinary vegetable. It yields a large reddish yellow fruit. A variety of *C. ovifera*, called succadee or vegetable marrow, is frequently cultivated for domestic use. It bears an oblong pale yellow fruit, which is either fried with butter or boiled and made into pies.

*Cucurbita lagenaria*, or more properly *Lagenaria vulgaris*, common calabash or bottle gourd, is found within the tropics, particularly in India, and yields an edible yellow fruit, having a whitish pulp. This fruit is sometimes six feet long and eighteen inches in circumference, and is called by the Arabians *Charrah*. There are several varieties of the plant, such as the common gourd, the depressed and the turbinated bottle gourd, the congourde, and the trumpet gourd. The name of bottle gourd is given to it on account of the shape of the fruit, and the use to which it is applied. In Jamaica and other warm countries, the dried outer coat or rind serves the purpose of water cups or bottles. The fruit is not often employed as an article of food, although it is tolerably good after being well cooked. The pulp is sometimes applied as a poultice, and the seeds are put to the same use as those of the genus *Cucumis*.

Gourds and calabashes are propagated by sowing their seeds in hotbeds in the month of April, afterwards transplanting them into beds with a moderate heat and plenty of moisture, and finally putting them on a dunghill and allowing them room to spread.

The genus *Momordica* is the next to which we shall turn our attention.

*Momordica elaterium*, wild cucumber, is a perennial plant found native in the south of Europe. It has been cultivated successfully in this country, but does not survive the winter. The fruit is oblong, about an inch and a half long, and an inch in thickness. It has a green colour, and is covered with thick rough hairs. When ripe, a slight touch separates it from the stalk, and the seeds and juice are scattered in all directions and with great force through the hole in the base where the footstalk was inserted. Hence the name *squirting* or *spurting cucumber* which has been given to the plant. The cause of this peculiarity in the opening of the seed vessel has not yet been fully ascertained, although many theories have been hazarded in regard to it. The seeds when fully ripe have a black colour, and are surrounded by a fluid from which the substance known in medicine by the name of *Elaterium* is produced. This drug is the fecula which subsides from the juice after the watery part is evaporated. In order to obtain it, the fruit is collected in the month of September before it is ripe, and is cut longitudinally, so as to allow the clear fluid to run out without pressure. By standing the liquid soon becomes turbid and deposits the elaterium, which is collected and dried without exposure to light.

When pure, elaterium should be in the form of thin cakes, of a light green colour, without any odour, and

having a bitter and slightly acrid taste. If it is nearly black, compact, and heavy, and breaks with a shining resinous fracture, it should be rejected as bad. It is often mixed with starch, an adulteration which it is sometimes not easy to detect by its appearance.

Elatarium consists of water, extractive, fecula, gluten, woody matter, and *Elatrine*. The latter substance, which is the active principle of the drug, was discovered by Dr. I. D. Monies, and is totally different from the *Elatin* of Dr. Paris. It is a white crystalline substance, of an extremely bitter taste, insoluble in water, but soluble in alcohol. It is easily procured from the alcoholic tincture of elaterium by evaporating it to the consistence of thin oil, and while still warm throwing it into boiling distilled water.

Elatarium is a powerful or drastic purgative, which is prescribed with good effect in cases of dropsy. It was known to the ancient physicians, and was used by them occasionally. When pure, it may be given in doses of one sixth or half a grain, and its effects should be carefully watched, as they are apt to be too powerful. *Elatrine* acts well in the dose of one-twelfth or one-sixteenth of a grain, and is much more certain than elaterium itself. The elaterium imported from *Mato* frequently requires to be administered in doses of two or three grains before it will act.

*Momordica balsamina*, balsam apple, is a native of India, and was introduced into Britain in 1568. It has a fleshy ovate fruit, which, when ripe, is of a red colour, and bursts irregularly so as to disperse the seeds. It is famous in Syria for curing wounds.

*Bryonia* is the only British genus of the order, and it contains a very large number of species, almost entirely exotic.

*Bryonia dioica*, red-berried bryony or wild vine, is frequent in thickets and hedges in England, but is scarcely indigenous in Scotland. It has a very large white root, and a slender climbing stem, and bears whitish flowers, which are succeeded by berries of a red colour.

The plant abounds in a fetid acrid juice. The root has a disagreeable taste and decidedly purgative properties, which are not lost by drying. When applied externally to the skin, it causes redness, and if the application is long continued it will induce inflammation. It was much used in ancient times as a violent purgative in cases of dropsy and insanity. When dried and powdered, the root was administered in doses of thirty or forty grains. In the south of England it is still used as a laxative, after being infused in gin. It is not, however, employed to any extent now-a-days in medicine, in consequence of the violent and even dangerous nature of its action. In large doses it is an acrid poison, and produces death speedily.

Bryony root consists of resinous and gummy matter, starch, albumen, extractive matter, vegetable fibre, water, several salts, and a peculiar principle to which the name of *Bryonine* has been given. This substance has a reddish-yellow colour and an intensely bitter taste, and has been considered the active ingredient of the plant. It is soluble in water and alcohol, and appears to be analogous to *Cathartine*.

The fecula contained in the root of the bryony, when separated from the bitter principle, may be used as nutriment. Cooking has a great effect, on the properties of the plant, rendering it wholesome and depriving it of its purgative qualities.

The root of *Bryonia rostrata*, beaked bryony, is prescribed in India internally in piles. It also possesses demulcent qualities, and has been recommended in asthmatic complaints.

The root of *Bryonia epigæa*, air-living bryony (so called from living in the air and throwing out shoots readily in that situation), was formerly considered as calamba root, which it resembles in quality.

The root of *Bryonia cordifolia* is reckoned cooling.

*Bryonia callosa* yields small bitter seeds, which are prescribed by the native practitioners of India in cases of worms, and also as a veterinary medicine. A fixed oil is procured from them, which is used for lamps.

It only remains for us to notice a few remaining genera, in order to complete the history of this important family.

The leaves of *Feuillea* or *Nhandiroba cordifolia* are said to be antidotes to vegetable poisons, even to such powerful poisons as strychnia.

The fruit of *Trichosanthes palmata*, palmate snake gourd, when powdered and mixed with warm coconut oil, is used in India for healing sores which occur in the ears and nostrils.

The fruit of *Benincasa cerifera*, wax-bearing gourd, is covered with a waxy substance, which is most abundant at the time when it becomes ripe.

*Joliffia Africana* or *Telfairia pedata* is an African plant yielding a fleshy fruit, three feet long and often eight inches in diameter. It is filled with seeds as large as chestnuts, which are said to have the flavour of almonds, and to yield abundance of oil equal to the finest olive oil.

CULICIDÆ. A family of dipterous insects, belonging to the section *Nemocera*, and having for its type the genus *Culex* of Linnæus, or the blood-thirsty gnat. This family occupies the foremost range amongst dipterous insects, on account of the more complete development of the organs of the mouth and antennæ. Indeed, it is not surprising, when we examine the structure of the gnat, that, even in the time of Pliny, this insect should have been selected as affording an admirable example of the wonders of the creation. "Ubi tot sensus collocavit ut in culice?" observes this father of natural history; and when we notice the beautiful organisation of the proboscis, that fearful organ which causes us so much pain, we immediately perceive its superiority, or rather the more complete development which it exhibits over the mouths of other diptera, except the *Tabanidæ*. This apparatus, although it appears to the naked eye like a long, slender, simple and single organ, consists, in fact, of a considerable number of fine lancet-like pieces, enclosed in a fleshy gutter, forming an instrument admirably fitted for suction, and provided with a poisonous liquid, which it instils into the wound it makes, and which is supposed to have the effect of causing the blood to flow more freely. Overlooking the beautiful organisation which this insect exhibits, how often is it that, in our rage, we destroy, or at least attempt to destroy, the gnat, which has feasted at the expense of our blood? How seldom is it that, like Reaumur, we have patiently allowed it to make its attack upon us, in order to watch the curious operation by which the blood is pumped up into its stomach from our hand. In every quarter of the globe, the gnat or mosquito, for the terms are nearly synonymous, does not cease day and night to attack us; and there is scarcely a spot on which they do

not abound. It has been considered by Isidore of Seville, that the name is a contraction of "Cutilex, quod cutem laciāt," an ingenious supposition, and one fully confirmed by the habits of the species. Nevertheless, this thirst for blood is exhibited only by the female; and in default of this fluid, this sex, as well as the males, content themselves with the honey of flowers. It would seem, also, that all the species are not similarly obnoxious, since Linnæus affirms that *Anopheles bifurcatus* does not prick with its proboscis. These insects seldom appear by day, except in dark woods, seemingly affected by the sun's rays. At twilight, however, they sally forth to pursue their blood-thirsty operations, and it is at this period that they assemble in swarms in the air for the purpose of coupling. Shortly afterwards, the females deposit their eggs in a very remarkable manner. The larvæ are destined to live in the water. The gnat is an aerial being. Taking its station, therefore, at the extremity of some floating leaf, the female deposits her eggs, one by one, attaching them together, and forming them, with the assistance of her hind legs, into a curiously contrived boat-like mass, which floats upon the surface of the water. These eggs hatch in the course of a couple of days. The larvæ considerably resemble those of some other *Nemocera* having aquatic larvæ (see *CHIRONOMUS*), differing, however, in several respects. The body is long, and furnished at the sides with long hairs; the head distinct and rounded, with two long ciliated jaws, which are kept in continual motion, serving for producing a current of water, which brings various small floating particles in contact with the mouth, which serve for the food of the larvæ; the mouth is also furnished with two long palpi, ornamented with whorls of hairs, and, with these exceptions, the body possesses no other distinct organs for locomotion; the last joint of the body is elongated, and furnished on one side with a long tube, placed at an angle, and enclosing a breathing apparatus. The extremity of this tube, and of the tail itself, is ornamented with a coronet of hairs, coated with an oily matter, and serving to repel the water; hence, when the larvæ takes its station at the surface of the water, for the purpose of obtaining a fresh supply of air, these hairs expanding, serve as a kind of buoy for retaining the insect in such position. These larvæ are small semi-transparent animals, which may be seen throughout the summer in ditches, or other standing water, jerking about with much rapidity. When the larvæ wishes to descend, it contracts the hairs of the buoys above mentioned, enclosing a bubble of air for future use in respiration. They are transformed into pupæ in about fifteen days; the front, or thoracic part of the body, is now thickened, and exhibits beneath the rudiments of legs and wings, enclosed in a general covering, and the hind part of the body curved towards the breast; instead of the posterior tube of the larvæ, its external breathing apparatus now consists of two anterior small horns, like those of the pupa of the chironomus. It jerks about in the water with much agility by the assistance of two small swimmerets, or little oars, at the extremity of the body, and two long hairs.

But, how is this aquatic animal, unprovided with legs or wings, able to creep along the sides of the bank, or up the stem of any growing plant, to escape out of the midst of the water, casting off a form which it could not live with in the air, and assuming one which would be destroyed if it remained in the water?

This question would puzzle any person but a naturalist. The pupa, rising to the surface at the period when it wishes to cast off its pupa skin, elevates the front part of the thorax above the level of the water, when instantly, by swelling the exposed part, the skin bursts, and the head of the gnat appears, followed by the thorax, which, from its increased size, enlarges the slit, so as to allow the rest of the body to follow with greater ease. At this critical period, the old skin of the pupa, which is of course now hollow in some places, serves as a support; in fact, it becomes in every sense a life-boat to the little animal. "The observer, who sees how the little boat gradually sinks, and how its margin approaches the water, forgets the mischievous insect it contains, which, at another time, he would crush without remorse, and becomes interested for its fate, especially should wind agitate the water. If it should upset, it would be all over with it, and numbers do thus perish. The gnat, after having fixed itself thus perpendicularly, draws first its two anterior legs out of their case\*, and moves them forward, and next the two intermediate ones; then, inclining itself towards the water, it rests itself upon it; for water is to them a soil sufficiently firm and solid for support, although surcharged with the weight of the insects; for, as soon as it is thus upon the water, it is in safety, its wings unfold themselves, and are dried, and it flies away. This is the work of an instant."—Introduct. to Ent. vol. iii. 288.

*Culex pipiens*, female, natural size, and magnified, with the head of the male.

The genera belonging to this family are *Anopheles*, *Culex*, and *Edes*; founded chiefly upon the length of the palpi, together with *Sabethes* and *Megarhina*. The two first only are British. There are about twenty British species belonging to the genus *Culex* (including the type *C. pipiens*, Linnæus), and four belonging to *Anopheles*.

**CULICIFORMES (Latr.)** A division of dipterous insects, belonging to the section *Nemocera*, and family *Tipulide*, and comprising many minute species, generally called midges, having, as the name implies, great resemblance with the insects composing the family *Culicidæ*, or true gnats, but differing from them, in wanting a long and asserted proboscis, the mouth consisting only of two short dilated fleshy lips, and a pair of short palpi. The antennæ are much ornamented with whorls of hair, which, in the males, are often as long as the entire antennæ, and form beautiful objects. The ocelli are wanting, and the eyes are crescent-shaped; the body is long, and the legs slender, the tibiae not being spined at the extremity. Here belong the genera *Tanyptus*, *Chironomus* (which

\* A recent writer has criticised the authors from whence we have extracted this passage, stating, that Kirby and Spence, by mistake, say it draws these out of their case. (Tras. Miscell. p. 19.) Had he been aware that the legs of dipterous insects are enclosed in distinct cases, although sometimes closely applied to the body, he would not have been so rash. Compare Swammerdam, pl. 31, fig. 8, d, and pl. 41, fig. 4, d.

see); *Sphaeromias*, and *Corethra*, Meigen. The latter genus is distinguished from *Chironomus*, by having the antennæ composed of fourteen oval joints in both sexes, the terminal ones being but little different from those at the base of these organs. The wings, when at rest, are laid horizontally upon the back. The type of the genus (which comprises but very few species) is the *Tipula culiciformis* of De Geer, by whom the history of this species has been traced through its different stages. Reaumur likewise found the larvæ of another straw-coloured species (*C. plumicornis*), in July and August, in standing water. Its body is crystalline and transparent, long, nearly cylindric, and rather thickened at its anterior part; the head is furnished in front with two recurved jointed hooks; and the tail is armed beneath with an oval plumed apparatus, for swimming or respiration, and at the tip with two hooks. The nearer this crystalline larva (which is a beautiful microscopic object) is to its transformation, the more distinctly four kidney-shaped bodies are perceived, two in the front part of the second, and two in the ninth segments of the body. It has been stated, in the Insect Transformations, that the latter perhaps serve to increase the tail-fins of the pupa, and the former the horns of the pupa, which again encase the antennæ of the gnat (midge), both which statements appear to us quite untenable; because the tail-fins of the pupa, being attached to its terminal segment, would necessarily be covered by the terminal segment of the larvæ, whilst the antennæ are laid along the breast, the "antennæ cases," as they are miscalled, arising from the thorax. It is more probable that the anterior pair of these bodies may, as De Geer conjectures (vol. vi. p. 395), be air-reservoirs, which, when the insect assumes the pupa state, become external, and are transformed into the horns in front of its body. Moreover, analogy induces us to adopt this opinion, as the same organs are found employed in respiration in the pupa of the gnat. Like most larvæ, the one which we are now describing sheds its skin. In like manner, it seems clear, from the statement of Reaumur, that the skin is also cast on assuming the pupa state, as he found exuvie at the bottom of the glass in which he kept them. The pupa is oblong, with the thorax bulging out, and having two small horns placed upon the front of the back; the head is closely applied to the front of the breast, with the antennæ lying behind the eyes, and the legs placed along the breast, enclosed in short cases. The tail is long, and gradually tapering to the tip, which is furnished with two elliptic-shaped plates employed in swimming. In this state it is very active, jerking about with great agility, especially when the time for assuming the perfect state approaches. It, however, usually keeps close to the surface of the water, so as to be able to project the thoracic horns above it, so that they are exposed to the air, an evident proof of their being employed as organs of respiration. The insect remains in this state ten or twelve days, when it assumes the perfect winged state.

**CULLUMIA** (R. Brown). A genus of ornamental shrubs from the Cape of Good Hope, belonging to the order *Compositæ*. Generic characters: anthodium of one leaf, thickly set with scales. Receptacle favose, seeds smooth; pappus none. This plant is curious, and easily kept and propagated in green-houses under ordinary management.

**CULTRIROSTRA**, a sub-order of stilt birds, characterised by the bill being long, strong, and knife-shaped. It includes the cranes, storks, herons, and some of the allied genera. See Bird.

**CUMMINGIA** (D. Don). An elegant, bulbous-stemmed plant, introduced into this country from Chili. Linnæan class and order *Hexandria Monogynia*, and natural order *Asphodelaceæ*. Generic character: calyx, bell-shaped, six-cleft, nearly regular, spreading; stamens inserted in the base of the corolla; filaments very short, united in a ring; anthers forming a cone, with cleft processes at top; style awl-shaped; capsule three-celled, three-valved, with many seeds. This is the *Conanthera campanulata* of Ruiz and Pavon, and of several other authors. Three species are already known, and they succeed when managed like other tender bulbs, that is, planted in a frame or pit, or on a warm border; the bulbs to be taken up before winter, and planted again in February. They are increased by seeds and offsets.

**CUMINIUM** (Linnaeus). An odoriferous plant, cultivated for its peculiar qualities as seasoning in cookery, and as a medicine. It belongs to the natural order *Umbelliferae*. In this country it only requires sowing in the open ground, with other annual herbs.

**CUNNINGHAMIA** (R. Brown). A fine ornamental forest tree, introduced from China. It belongs to the class *Monocotyledonæ*, and to the natural order *Coniferae*. This is the *Pinus lanceolata* of Lambert, and the *Bellis jaculifolia* of Salisbury.

**CUNONIACEÆ**. A natural order of dicotyledonous plants, containing eight genera and forty-four known species. It is closely allied to *Saxifrageæ*, and by many botanists is considered merely a section of that order. It differs, however, in its shrubby habit and its remarkable interpetiolar stipules. It bears also an affinity to *Bauera*, from which it is distinguished by its definite stamens and the presence of stipules.

The characters of the order are: calyx four or five-cleft, half superior; petals four or five, occasionally wanting; stamens eight to ten, perigynous and definite; ovary two-celled, the cells having two or many seeds; styles one or two; fruit two-celled, capsular or indehiscent; embryo in the axis of fleshy albumen. The plants belonging to the order are trees or shrubs with opposite, compound, or simple leaves, interpetiolar stipules, and white or red flowers.

They are found at the Cape of Good Hope, in South America, the East and West Indies, and New Holland.

Little is known in regard to their properties. The chief genera of the order are: *Cunonia*, *Weinmannia*, *Callicoma*, *Dieterica*, *Ceratopetalum*, and *Arnoldia*.

Of the genus *Weinmannia*, there are thirty-one known species, most of which possess astringent qualities: one of the species is used in Peru for tanning leather, and its bark is employed to adulterate Peruvian bark.

**CUPANIA** (Linnaeus). A genus of lofty tropical trees, belonging to the eighth class and first order of the sexual system, and to the natural order *Sapindaceæ*. Generic character: calyx of five sepals; petals cupped or flatish; filaments awl-shaped; sometimes long, but frequently very short; anthers incumbent; style trifid; stigma obtuse; capsule leathery, and three-celled, three-valved; cells one or two seeded, seeds winged. This tree is cultivated

in our stoves, is grown in loam and moor-earth, and is propagated by ripened cuttings struck in sand, and a little heat.

**CUPHEA** (R. Brown). A genus of greenhouse, annuals, and hothouse under-shrubs, natives of the West Indies. Linnæan class and order *Dodecandria Monogynia*, and natural order *Salicaria*. Generic character: calyx tubular, swollen at the base; limb from six to twelve-toothed, the upper tooth broad; petals six, inserted in the calyx; stamens from ten to fourteen, fixed to the throat of the calyx, unequal; anthers two-celled; style filiform; stigma simple or two-lobed, bottom of the ovarium glandular; capsule covered by the calyx, one-celled; seeds like lentils. The annual species may be sown in the open ground, like other annuals; and the biennial sorts should be raised on heat, put into pots, and kept in the greenhouse or stove.

**CUPRESSUS** (Linnæus). A genus of ornamental evergreen trees, commonly called cypress. They belong to the twenty-first class of Linnæus, and to the natural order *Coniferae*. A few of this genus are kept and propagated and managed like other greenhouse plants. The hardy sorts are raised from seeds, and nursed in pots till fit to be planted on lawns or other parts of ornamented ground. When young they are tender, and liable to be killed by severe frost; but in favourable situations, as in the south of England, and in all warmer countries, they gain a considerable height, and are very conspicuous trees. They were anciently, as well as at present, in south-eastern Europe, chosen as memorials of the dead; and still are the principal ornaments of cemeteries in Greece and over all the Ottoman empire.

**CUPULIFERÆ**—The oak family. A natural order of dicotyledonous plants, containing five or six genera, and numerous important species. It is allied to the willow and birch families, but is distinguished from the former by the veining of its leaves, and from the latter by the presence of a calyx. It bears also an affinity to *Urticeæ*, but differs in its many-celled ovary, pendulous ovules, and superior calyx. By many botanists this order is considered merely as a section of *Amentaceæ*. The name *Cupuliferae* is derived from the peculiar husk, or cup (*cupule*), in which the fruit is enclosed.

The essential characters are: flowers unisexual; male ones amentaceous, with from five to twenty stamens, which are generally distinct, and are inserted into the base of the scales, or perianth; female ones aggregate, or amentaceous; ovaries crowned by the rudiments of a superior calyx, seated within a coriaceous involucre, variously formed, and with several cells and ovules, the greater number of which are abortive; ovules twin, or solitary, pendulous; stigmas several, nearly sessile, distinct; fruit, a horny, or coriaceous, one-celled nut, more or less enclosed in the enlarged involucre (*cupule*); seeds solitary, two to three, pendulous; embryo large, with plano-convex, fleshy cotyledons, and a minute superior radicle.

The plants belonging to this order are trees or shrubs, having alternate simple stipulate leaves, with veins proceeding straight from the midrib to the margin. They inhabit chiefly the temperate parts of the northern hemisphere, and form extensive forests both in the old and new world. They are common in Europe, Asia, and North America, and they are also found in some parts of South America, and in the northern parts of Africa. They are said to be

totally unknown at the Cape of Good Hope. Some of the species grow on the high lands of tropical regions.

The order furnishes many trees which are highly valued on account of their timber. Its medicinal properties in general may be said to be astringent and tonic, and it includes some plants which are used in the arts, and others which are employed as articles of materia medica.

The chief genera are, *Quercus*, or oak; *Castanea*, or chestnut; *Fagus*, or beech; and *Corylus*, or hazel nut.

The genus *Quercus*, or oak, belongs to the class *Monæcia*, order *Polyandria* of the Linnæan system, and is well known as supplying many important species of forest trees. According to Michaux, there are at least forty-four species of the genus in America, confined entirely to the northern hemisphere, extending from the 48th to the 20th degree of latitude; while in the old world there are upwards of thirty species, which grow both in the northern and southern parts, from the 60th degree of north latitude. The species have been divided by him into separate sections, according as the fructification is annual or biennial; and the different forms of the leaves have furnished him with a means of further subdivision.

Of all the species, the *Quercus robur*, or *pedunculata*, of some foreign authors, the common British oak demands our first attention, whether we consider the dignity of its stature, or the variety of uses to which it is applied. It is the king of our forests, excelling all other trees in the beauty of its growth; the thickness of its trunk, and the hardness and solidity of its wood. It constitutes the greatest part of the European forests, extending from the 60th to the 35th degree of latitude. It is indigenous in our island, and grows well in almost any soil, and even in the most exposed situations. It delights in rich deep earth, but the finest grained timber is said to be produced in sandy soils. It is found both in forests and hedgerows, but succeeds best in the former. The flowers appear in spring, but the exact time at which the leaves and flowers expand varies much, according to the situation and soil in which the tree grows. Sometimes we notice one oak in full leaf, and another, not far from it, without any such appearance, owing to the coldness or barrenness of the soil in which it has been planted. The leaves are generally put forth at a later period than those of other trees, but they continue longer green.

The oak is usually raised from its seeds, which are ripened in October, and well known by the name of acorns. These may be either sown at once in the place where the oaks are to remain, or in a nursery, and the young trees subsequently planted out. They are sown in the spring or autumn, in loamy well prepared soil, and the young plants generally appear above ground in the course of six weeks. If reared in a nursery, they may be planted out in the course of two years, and considerable care is necessary in keeping the ground clean, and free from weeds. The plants, in the first instance, are set in rows, four feet asunder, and two feet distant in the rows, and after twelve or fourteen years, every second plant is taken out, and sold for hoops, or small poles. After seven or eight years more, another thinning may be practised, the strongest and most vigorous trees being left to form timber at the distance of twenty or thirty feet from each other. The plantations should be

sheltered by means of Scotch fir, or other hardy quick-growing trees. On the judicious thinning and clearing of a young wood, as well as protecting it from the severity of the climate, depends much of a planter's success and profit. The oak might be cultivated very profitably on many waste lands situated near rivers or navigable canals. When the acorns are sown in a field, and the trees allowed to grow naturally, we secure the best timber for the use of the carpenter and ship-builder, and in a much shorter time than if the plants are first raised in a nursery, and then transplanted.

The oak attains a great age, and is said not to reach maturity till it is one hundred years old. Some of the aboriginal oaks of this country have been known to exist for a thousand years. The oak against which the arrow of Walter Tyrrel glanced, before it killed William Rufus, was in existence less than a century ago; and there is still seen at Torwood, in Stirlingshire, the oak under which the famous Wallace convened his followers.

The oak sometimes requires the height of 100 feet, more especially when planted in woods. Its trunk also attains a great degree of thickness. The trunk of an oak growing in 1764 in Broomfield wood, Shropshire, was sixty-eight feet in circumference and twenty-three feet in length. The tree was estimated to contain 1455 feet of thick timber. The circumference of the green dale oak, near Welbeck, at eleven feet from the ground, was thirty-eight feet, and one growing near Wetherly, in Yorkshire, measured seventy-eight feet close to the ground. Dr. Thomson mentions that an oak was felled at Whitby Park, Shropshire, in 1697, which was nine feet in diameter without the bark; its branches spread 144 feet, and twenty-eight tons of timber were contained in the body of the tree. Dr. Plott mentions an oak, at Norbury, which was forty-five feet in circumference, and when it was felled and lying on the ground, a horseman on one side of the trunk was completely concealed from one on the other side.

While the tree thus attains a great height and thickness, it also sends its roots deeply into the ground, and is thus enabled to resist the shocks of tempests and the war of elements.

As o'er the aerial Alps, sublimely spread  
Some aged oak uprears his reverend head,  
This way and that the furious tempests blow,  
To lay the monarch of the mountain low;  
Th' imperial plant, though nodding at the sound,  
Though all his scattered honours strew the ground,  
Safe in his strength, and seated on the rock,  
In naked majesty defies the shock;  
High as the head shoots towering to the skies,  
So deep the root in earth's foundation lies.

The oak is a very valuable forest tree, and is much cultivated on account of the timber and bark which it furnishes. Houses and ships, cities and navies, are formed of it. To it we are indebted not only for our maritime glory and commercial prosperity, but also for many of the ordinary comforts of life.

From a small acorn see the oak arise,  
Supremely tall and towering to the skies!  
Queen of the groves, her stately head she rears,  
Her bulk increasing with increasing years!  
Now moves in pomp majestic o'er the deep,  
While in her womb Britannia's thunders sleep;  
With fame and conquest graces Albion's shore,  
And guards the island where she grew before.

The oak was held sacred by the Greeks and Romans as well as the ancient Britons. By the

Romans it was dedicated to Jupiter, and in former times Druidical ceremonies were frequently performed under its shade. The fruit of the oak was used in the early ages of the world as an article of food, and the failure of the acorn crop was considered as a cause of famine. Now-a-days acorns are given as food to hogs, squirrels, and the larger gallinaceous birds, and are said to have a great effect in fattening them. The root of the oak is beautifully grained, and is employed for many useful and ornamental purposes. All the parts of the oak are astringent, but the bark possesses this property in a remarkable degree, and is on this account used officinally. Oak bark is covered with a bluish-grey epidermis, and within is of a red colour. It is peeled in spring, when it is more astringent than in the later part of the season. Its astringency is owing to the presence of gallic acid and tannin, which exist in great quantity in the inner part of the bark. As a powerful astringent, it is given internally in powder, in doses of from two to six drachms. It may be used as a substitute for cinchona bark in the cure of ague, and has been administered to stop internal hæmorrhages and bleeding from the nose and mouth. The decoction of the bark is used as a gargle in relaxed sore throats, and as a lotion to indolent ulcers. An extract of the bark is also prepared for medicinal use.

The use of the bark in tanning leather is familiar to all, and its employment in the construction of hot-beds is also well known. The saw-dust of the oak is used in dyeing all the varieties of drab and the different shades of brown. An infusion of the bark with a small quantity of sulphate of iron is employed by common people to dye woollen stuffs of a purplish colour.

Acorns and their cups when roasted are administered either in the form of powder or infusion in cases of bowel complaint and passive hæmorrhages.

The only other British species of the genus is *Quercus sessiliflora*. The specific name is apt to mislead, inasmuch as the flowers in both species are sessile. In the common oak, however, the catkin is on a long footstalk, while in the present species it is nearly sessile. The timber of this species is generally considered inferior to that of the *Quercus robur*.

*Quercus suber*, the cork tree, is a tree about forty feet high, which grows in the south of France, in Spain, Portugal, Italy, and the north of Africa, between the thirty-fifth and forty-fourth degrees of latitude. Its leaves continue green till the middle of May, when they generally fall just before the new leaves appear. It yields oval acorns like those of the common oak, which are eaten by hogs with avidity. Its timber is heavy, hard, and compact, but not very durable. The tree is chiefly valuable on account of its bark, the external layer of which furnishes the light, elastic, and impermeable substance called *Cork*, which is applied to so many important uses. The bark is taken off every eight or ten years, and the trees will often live for 150 years, even though the process of removing their bark is repeated regularly. When young, the tree does not yield good cork, and the two first peelings are in general not fit for use. It is only when the trees are about forty years old that the bark becomes valuable. The stripping of the bark takes place in the months of July and August. Two incisions are made parallel to each other along the whole length of the tree, and then two others are made transversely at the extremities. The outer bark is then removed, care being

taken not to injure the inner cortical layer, otherwise no new bark would be produced. After being taken off, the bark is flattened by exposing its convex surface to heat and pressure. It is also charred on both sides, so as to close the transverse pores before being sold. The carbonised surfaces are seen in bungs and taps, but not in ordinary corks which are cut lengthwise. The bark gathered in France has been estimated as sufficient to form 119,000,000 or 120,000,000 of corks eighteen lines long.

Cork was used by the Greeks for sandals, and is occasionally employed now-a-days for lining the soles of shoes. It is also employed to form surgical instruments and apparatus, and is essential to the cabinet of the entomologist.

The charcoal got from it, when mixed with lard, has been recommended in piles. It contains a peculiar principle called *Suberin*, and an acid called *Suberic acid*.

*Quercus tinctoria* is an American tree which attains the height of eighty or ninety feet with a diameter of four or five feet. It supplies useful timber, and its bark is used for tanning leather. The cellular part of the bark furnishes *quercitron*, a substance used for dyeing wool and silk of a yellow colour. It is said to be superior to woad. The decoction of quercitron has a brownish yellow colour, which is rendered deeper by alkalies.

*Quercus coccifera*, the kermes oak, grows plentifully in Spain, Provence, Languedoc, and along the coast of the Mediterranean. It is a tree of small growth, being in general not more than twelve feet high. Its acorns are smaller than those of the common oak. From this tree is gathered the vegetable kermes, an insect with which the ancients used to dye their garments of a beautiful pink colour. Since the discovery of America, the *coccus cacti*, or cochineal insect, has supplied the place of the kermes.

Kermes is met with in commerce in the form of little red globular grains torn on the side where the animal adhered to the leaves or young branches of the oak. According to analysis it consists of yellow fatty matter, red colouring matter analogous to carmine; coccine, a peculiar animal matter, and various phosphates and muriates. The colour obtained from the kermes is said to be more fixed than that got from the Mexican insect.

*Quercus esculus*, cut-leaved Italian oak, is the small oak or phagus of the Greeks, and the *Esculus* of Pliny. It is a native of Spain and Italy, and was used by the Romans to form their civic crowns. Its acorns are sweet, and are frequently eaten by the poor in the South of France, who, in times of scarcity, grind them and make bread with the flour.

*Quercus rubra*, red oak, is a native of Virginia and other parts of North America. It extends far north, and grows to the height of eighty feet. It yields large acorns, which are eaten by wild animals, as well as by horses, cows and hogs. Its bark is employed for tanning, but its wood is not much used in building.

*Quercus alba*. White oak, so called on account of the whiteness of its bark; is a native of North America, where it reaches the height of seventy or eighty feet, with a diameter of six or seven feet. Its wood is considered in America preferable to any other sort for building, on account of its strength and durability. The wooden bridge which joins Cambridge and Boston, and which is nearly 3000 feet long, is supported by posts of white oak from fourteen to fifty feet long.

Its bark contains a considerable quantity of tannin, and an infusion of it has been known to cure ague. Its acorns are large, oval, and sweet.

*Quercus virens*. Live oak, found in Carolina and Virginia; yields small acorns, which are eaten by the Indians, and are used by them to furnish a sort of oil. The acorns of *Quercus ilex*, evergreen oak, are mild and nutritive, and serve for food. The acorns of *Quercus agrifolia*, a native of Spain and the Levant, where it is called *Velonia*, are imported as a dye-stuff.

Many other species of oak might be noticed, such as black oak, scarlet oak, willow oak, chestnut oak, laurel oak, dwarf oak, water oak, &c., most of which are cultivated either on account of their wood or bark; but it appears unnecessary to dwell longer on the subject, inasmuch as the properties of the oak tribe have been already sufficiently illustrated by the examples which have been adduced. Before, however, proceeding to treat of another genus, we shall make a few remarks on a disease to which the oak is subject, in consequence of the attacks of insects.

The leaves, flowers, and fruit of almost all vegetables are liable to be attacked by the insect tribe;

The flowery leaf  
Wants not its soft inhabitant. Secure  
Within its winding citadel the stove  
Holds multitudes. But chief the forest boughs  
That dance unnumber'd to the playful breeze,  
The downy orchard and the melting pulp  
Of mellow fruit, the nameless nations feed  
Of evanescent insects.

In some cases their attack is followed by the production of a peculiar substance, which is turned to useful account in a medical or economical point of view, and of this we have an excellent illustration in the genus now under consideration. Upon the leaves of all the species of oak there are found globular bodies, to which the name of galls, or gall-nuts, has been given. They are produced by various small four-winged insects, denominated *Cynips quercusfolii*, or *Diplotlepis gallicæ tinctoriæ*, &c. The adult female insect is furnished with a long slender spiral sting, with which it punctures the stalk of the oak-leaf, and at the same time deposits a minute egg, and probably some irritating fluid. In consequence of the irritation, which is produced by this wound, the sap is determined to the part, and the extravasated juice flowing around the egg soon forms a soft excrescence, which serves both for the shelter and food of the young insect. The tumour increases very rapidly, until a perfect gall is formed. The larva afterwards issues from the egg, assumes the pupa state, and then escapes as the perfect fly, by perforating the walls of the chamber in which it is inclosed.

The best galls are those which are gathered before the insect has escaped, and are denominated black, blue, or green galls, on account of their colours. There is of course no perforation in them, and on opening them we find perfect specimens of the fly. Those galls, on the contrary, which are collected after the fly has escaped, are called white galls, and are not so much esteemed, containing less astringent principle than the entire galls in the proportion of two to three.

The oak on which the finest galls are found is described by Olivier, in his *Travels in the Ottoman Empire*, as the *Quercus infectoria*, a small tree growing in Asia Minor. The galls are collected by the poorer inhabitants, and are exported from Smyrna, Aleppo, and various parts of the Levant.

Oak-galls have a round globular form, and vary in size from that of a pea to that of a hazel nut. They contain, according to Sir Humphrey Davy, tannin, gallic acid, mucilage, saline, and earthy matter. A remarkable difference exists between the chemical properties of the oak-bark and nut-galls, the latter precipitating tartar emetic and infusion of cinchona, which are not acted on by the former. Water dissolves all the active matter of galls. The solution for medicinal use ought to be prepared by simply infusing the galls in distilled water at the temperature of about 180°. In this way we procure all the gallic acid and tannin in solution, without a mixture of extractive, &c.

Galls are used in medicine, both externally and internally, as astringents. They are prescribed in the form of powder, infusion, tincture, or ointment. When administered internally, they are often mixed with aromatics, so as to render them more agreeable to the stomach. In this way they are used in India for the cure of intermittent fevers. The infusion is employed as a gargle for relaxed sore throats, and as an astringent lotion for ulcers, while the gall ointment is applied as a remedy for piles. The powder, in doses of ten or twenty grains, is perhaps the best form of administering this medicine. Some preparations made from galls are used as styptics, to stop bleeding from wounds, leech-bites, &c.

Galls are also employed in dyeing, and in the preparation of common ink. In allusion to the latter circumstance, it has been well remarked—"How infinitely we are indebted to this little creature (the gall-fly), which at once enables us to converse with our absent friends and connexions, be their distance from us ever so great, and supplies the means by which, to use the poet's language, we can

Give to airy nothing  
A local habitation and a name!

When any salt of iron is added to an infusion of galls, a black colour is immediately produced, and it is upon this principle that ink is manufactured, this valuable liquid being merely a decoction of galls, sulphate of iron or green vitriol, and logwood, with a little gum, which is added to give it a consistence.

The galls formed on the common oak, *quercus cerris*, and other species, are small, and smooth and reddish, and are not applied to use.

The next cupuliferous genus to which we shall allude is *Castanea*, chestnut.

*Castanea vulgaris*, or *vesca*, formerly *Fagus castanea*, the sweet, or Spanish chestnut, is a beautiful tree, the trunk of which often acquires a great size. It is stately and majestic, rivalling the oak in magnitude and duration. It is common both in this country and on the continent. Its flowers appear in long spikes about the month of June, and its fruit, which is enveloped in a husk defended by prickles, is ripened in September or October. The nuts which it yields are familiar to every one under the name of *chestnuts*. The bark of the tree is remarkable for its deep and wide clefts, which seem to have furnished ideas for some of the ornaments in Gothic architecture. The chestnut is not so picturesque as the oak, but it is sometimes introduced into the paintings of the old masters, more particularly those of Salvator Rosa.

Chestnut trees are remarkable for the age and size which they sometimes attain. At Tortworth, in

Gloucestershire, a chestnut tree grew in 1766, which was said to be upwards of one thousand years old. It was fifty-two feet in circumference, and was known to have served for a boundary-mark in the reign of King John, at which time it was five hundred years old. On Mount Ætna, in what is denominated the third, or woody region, there is a gigantic chestnut tree, known by the name of *Castagno de cento cavalli*, or chestnut of a hundred horse, because it was said to be capable of sheltering one hundred horses under its boughs. It is believed to be some thousand years old. It seems to consist of five large, and two small trunks, which, in all probability, formed only one originally, inasmuch as there is no bark on the inside of the trunks, nor on the sides that are opposite to one another. The largest trunk is thirty-eight feet in circumference, and the whole five taken together measure one hundred and ninety-six feet round. Although the interior is entirely decayed, and there is a wide public road through it, still the tree bears foliage, and even produces fruit. A hut is built within the trunk for the habitation of those who are engaged gathering and preserving the fruit. Several other large chestnut trees grow on the sides of Mount Ætna.

Chestnut wood was formerly in great repute for building. Evelyn mentions, that most of the ancient houses in London were built of it, and that a large forest of chestnuts existed in old times in the neighbourhood of that city. The church of St. Nicholas, at Great Yarmouth, erected in the reign of William Rufus, is roofed with chestnut. The wood serves also for various economical purposes. It is used for palisades, and props for vines and hops, as well as for water-works. Pipes bored of it, and lying constantly under ground, are said to be very durable. The Italians make casks and tuns for wine from this wood.

Chestnuts are mentioned by Virgil and Pliny as excellent articles of food. They are constantly used as such in the south of Europe at this day. Dr. Hooker states, that in some parts of France he has had them served up for breakfast boiled in milk. They are farinaceous, and when boiled have a sweet and agreeable taste. They consist of fecula, gluten, very analogous to that found in grasses, and a saccharine principle. They are used for whitening linen cloth, and for making starch. They are much relished by deer and swine.

There are several varieties of chestnut in cultivation. One of these, with striped leaves, is considered very ornamental. The trees are raised from the nuts, which are carefully selected, and placed in seed-beds in the month of February. In these they are allowed to remain for two years, and are then planted in rows, two or three feet apart, and a foot and a half distant in the rows. In the course of four or five years they may be planted out. This treatment is adopted when it is wished to produce fruit in abundance. If, however, the trees are intended for timber, they ought to remain in the spot where the seeds were originally sown, being merely thinned out, and kept free from weeds. Some, however, disapprove of this method, and think transplanting the best mode of rearing the tree, whether fruit or timber be desired. The chestnut succeeds well in almost any soil, but thrives best in rich loamy land.

*Castanea pumila*, the Chinquapin, or dwarf Virginian chestnut, is another species common in the

American woods, and attains a height of twelve or fourteen feet. It is a hardy tree, and produces abundance of nuts. It is sometimes cultivated in Britain.

The next genus for consideration is *Fagus*, or beech. *Fagus sylvatica*, the common beech-tree, is abundant in forests in the south of England, but is rarely found wild in Scotland. It is a handsome and valuable forest tree, putting forth green leaves, many of which, more especially when the tree has been clipped, remain during the winter, and assume a brown colour—

The red leaf  
Seared in autumn's breath, yet wearing well  
A garb to hail the coming winter in.

The leaves, after they fall, do not readily decay, and are used by the country people in France in place of straw for their beds.

The tree is either planted in woods or hedgerows, and sometimes attains a considerable height. Beech woods are peculiarly dry, and agreeable for walking, and are eagerly sought by the botanist, on account of the many rare orchideous plants which they contain. The leaves of the beech appear in April, and the flowers are produced in May. They are succeeded by an angular fruit, the size of a filbert, commonly called *beech-mast*, which is ripened in autumn. There are two varieties of beech, the one with dark red, the other with cut leaves.

The wood of the beech is hard and brittle, and is employed by cabinet-makers, turners, and wheelwrights. Carpenters' planes are made of it, and when split into thin layers, it forms scabbards for swords. The ancient shepherds carved their love verses on the green bark of the tree, and they used the wood for the manufacture of bows.

No wars did men molest,  
When only beechen bows were in request.

Beech nuts are sweet and agreeable, and have been used for food. When dried and powdered, they have been made into wholesome bread. They enabled the inhabitants of the island of Chios to endure a memorable siege. When roasted, they are sometimes used as a substitute for coffee. By expression, they yield a thick oil, which may be kept many years without becoming rancid. This oil is used for seasoning in some parts of France; and in Silesia the poor people make use of it in place of butter. Swine are driven in autumn into beech forests to feed upon the mast. The beech tree is propagated from seeds, and is treated in the same way as the oak and chestnut. It delights in a chalky and stony soil, and, when fully grown, affords an agreeable shade, as is beautifully noticed by Virgil in his First Eclogue. (For further particulars in regard to the cultivation of this tree, see article BEECH.)

Another genus, which is sometimes included under this order, is *Corylus*, or hazel. *Corylus avellana*, common hazel nut, grows abundantly in hedges and copses in all parts of Britain. It flowers early in spring, and ripens its fruit in September. The nuts, which are known by the name of filberts, are sweet, agreeable, and nutritive, and are common at our tables. Of the several varieties, the frizzled filbert is the best. The nuts contain a thick fixed oil, and are sometimes made into emulsions. The wood is used for various domestic and agricultural purposes. It forms good charcoal for drawing

The young forked twigs of the tree constitute the celebrated divining rod, which, in the ancient days of superstition, was employed to indicate the part of the soil in which metals and springs of water existed.

The hazel is generally raised from seed, and, in order to produce fruit abundantly, it is regularly pruned, and not allowed to attain a great height. The name hazel-nut is derived from two Anglo-Saxon words, *hasel*, a cap, and *knutu*, a nut. (We have already given a short notice of this tree under the article BETULINEÆ, in which order it is included by some authors.)

The members of this family bear a very strong resemblance to each other, both in their botanical characters and medical properties. In all of them the bark is bitter and astringent, and is used for dyeing, tanning, or for medical purposes. The wood is, in general, employed as a durable timber for building. While, in a few instances, the fruit is bitter and disagreeable, in the greater number it is farinaceous, and frequently contains an oily matter used in domestic economy. There are no poisonous plants in this family.

CURASSOW, or HOCCO—*Crax*. A genus of gallinaceous birds belonging to the family ALECTORIDÆ, under which some account of the characters of that family, and a list of the genera which compose it, will be found.

The generic characters of the present genus are: the bill strong, of mean length, compressed, higher than broad at the base; the upper mandible elevated, arched, curved from its origin, which is enveloped with a membrane; nostrils basal, lateral, and partly closed with membrane; head ornamented with a crest composed of feathers which are erect, but recurved at their points; tarsi long and without any spur; three toes to the front united at their bases by a small membrane, and one toe to the rear which reaches the ground in walking; wings short, concave, and rounded; the sixth quill being the longest; tail composed of twelve large feathers.

The *Alectoridæ* occupy the same place in the natural history of tropical America, which the *Gallinæ* do in that of tropical Asia; and among them the genus *Crax* answers to the genus *gallus*, or common domestic poultry. They are found only in the rich forests of South America, and are more equatorial in their habits than the turkeys, though in their localities the two genera border upon each other, and, of course, to a certain extent occupy the confines of each other's ground. Like the jungle fowl of the east, the Curassows (*Hocco*s is the preferable name, for Curassow is the trivial name of only one variety, and it is not a very happy one, being derived from the island of Curaçoa, in which we believe the birds are not found) are all perchers; though they all seek their food upon the ground. Like these, too, they are very impatient of rain, and their plumage is soon wetted; in fact there is in their whole economy a very great resemblance to the fowl of the east.

That the principal ground-feeding birds of the two most fertile regions of the world, which have nearly the same latitude, but are almost the antipodes of each other in point of longitude, should correspond so nearly in their general habits and economy, is an important point in natural history; because it establishes the connection which there is between the region and the inhabitants. It also lets us see why the gallinaceous birds of those rich tropical countries

which have strongly marked varieties of seasons, should be different from those of more temperate climates, and also of the more elevated and exposed places of the same climates. The gallinaceous birds which are indigenous to the latter situations, generally squat and nestle on the ground during the night as well as in nesting time; while those of the tropical forests are invariably perchers, have their wings short, broad, hollow, and rounded at the extremities, and their tails large and strong; so that, though they are not adapted for long flight, there are no birds which get more quickly or more easily on the wing, or fly more nearly in the perpendicular. This is necessary, in consequence of the greater abundance of enemies which these birds have on the ground than the birds of open places; and it is also necessary that they should perch, because during the rains the ground is often laid under water for several days.

In a wild state the curassows inhabit the most remote places of the forests, carefully shunning the settlements of the colonists and the huts of the natives; but though they are retired they are so far from being shy, that they fall an easy prey to the sportsman. There are, comparatively speaking, few birds of prey, in those close places, because there is no scope for their wings; and therefore the usual safety of the curassow is gaining a branch. Thus when the sportsman comes before a pack of them, for they are sociable and live in considerable packs, he can shoot as many as he chooses.

Like the corresponding races of the east, these birds seem to tell man in as plain language as nature can speak to him, that the places which they inhabit were made for him to cultivate, and that they themselves were made to live with him in a state of domestication. For, as soon as they are brought into the farm-yard, they become as confiding as they are timid when in a state of nature. They breed freely, have no disposition to wander, fatten well, and are very valuable for the table, as well for the quality as the quantity of their flesh. When in a state of nature, they are not nearly so prolific as our domestic poultry, the eggs in a hatch being only from four to six; but we believe that in all the species there are two broods in the year. There are, however, no animals, the fertility of which is so much affected by treatment as domestic birds, more especially poultry; and the number of eggs which a domestic hen will lay, even in the cold countries of Europe, is far greater than that which a wild hen of the very same species will lay in the jungles of South-eastern Asia. As household poultry the present genus of birds are very successfully cultivated in South America; but the attempts which have been made in Europe have not been so successful; so that the birds are rarely seen except in single specimens in the collections of exhibitors. What the cause of the failure may be is not very well known; and it is rather singular that the cultivation of them should fail, while the pullet and pea-fowl of Asia, the Guinea-fowl of Africa, and the Turkey of America, all thrive so well. We believe, however, that there is something in the quickness of the transition; for the Asiatic and African birds have come gradually, and were centuries on their march from their native localities to the west of Europe. The Turkey, though a much more northerly bird, was at first exceedingly difficult to rear; and, we believe, that it is still the most tender chick in the poultry-yard; and it is natural to suppose that if a bird of the

comparatively temperate parts of America is thus delicate, one of the tropical parts must be much more so. It is also probable that as, hitherto at least, those who have visited the native abodes of these birds, have had neither taste nor skill in natural history, we may be ignorant of some circumstances which prevent this very valuable addition from being made to the birds of our farm-yards. The principal disease which these birds have displayed in the attempts to rear them in Europe, has been a sort of mortification in the feet; but whether that has been caused by food or by locality has not been ascertained. In a state of nature, the birds are found on ground both hard and soft; and they make their nests indiscriminately on or under hillocks, in rifts of the rocks, and on the forks of thick branches of trees; so that it is not easy to draw any conclusion as to what sort of locality would suit them best. Their history deserves to be studied much more carefully than it has been, and more with a view to domestic economy than to mere systematic natural history. There are several species, of the leading ones of which we shall give a list; and as each of them has either two or three English names, or none, we shall give precedence to the systematic ones.

*CRAX CARUNCULATA*—Wattled Curassow. This species is found in Brazil. It is a large bird, from two feet and a half to three feet in length. The upper part black with green reflections, the belly brownish, and the bill and feet black. The upper mandible of the bill is much elevated, and furnished at the base with a red membrane, which descends at each side a little below the under line of the lower mandible. It is from this that the bird gets its name.

*CRAX RUERA*—Red Curassow. This is also a Mexican species, if, indeed, it be a species, and not a mere variety of the other. It is nearly of the same size as the former, and almost the only difference between them is in colour. The upper parts and the breast are of a red colour, marked with darker spots of the same; the head and neck are white, with a round black spot at the point of each feather; the feathers which form the crest are white with black borders; the under parts reddish; and the bill and

Red Curassow.

feet blackish ash. The young are mottled with white and black, and reddish, and have the black and the white on the head and neck reversed; the feathers of the crest straight, and the quills margined with white.

*CRAX ALECTOR*—Crested Curassow. This is the species which is generally referred to as being typical

of the genus; but it is not so any more than the others; and it is not more crested than they are, only its crest consists of feathers which are straight or nearly so, and broad at the tips, while in most of the other species those of the old birds are frizzled.

We may remark, *en passant*, that the use of the crest to these birds seems to be to protect their eyes from the beams of a nearly vertical sun, which otherwise would prevent them from finding their food. The upper part of this species is streaked with white and reddish; the breast, the belly, and the thighs are bright russet-red, crossed by black bands; and the rest of the under parts entirely russet; the bill is whitish, and the feet reddish ash. These are the colours of the young birds before they attain their full size. The native birds are entirely black on the upper part, with iridescent reflections; pure white on the belly and under tail coverts; but the colours are subject to variation. The bill and feet are blackish, the membrane of the bill and the naked space round the eyes blackish yellow. The size is rather less than the former species, though as domesticated there are great differences.

*CRAX GLOBICERA*—Lumped Curassow. The distinguishing character of this species is, a round protuberance or knob on the upper mandible, immediately in front of the membrane. The upper part, and indeed the whole plumage with the exception of the belly, the lower tail coverts, and the tips of the wing coverts, all of which are pure white, is black, with various reflections. The membrane at the base of the bill yellow, the bill and feet black. The young have the prominence on the upper mandible very small, and streaked and mottled with black and white.

Such are the leading species or varieties, as usually noticed by naturalists; but it is doubtful whether these be any more than mere climatal varieties; for we believe that they all breed readily with each other; they are all nearly of the same size, and their manners are exactly similar.

*CURATELLA* (Linnaeus). So called because its rough leaves are used in Guiana for polishing wood. The genus belongs to *Polyandria Digynia*, and to the natural order *Dillenaceae*. Generic character: calyx of four or five sepals, persisting, sepals roundish, unequal; petals rounded, hollow; stamens inserted in the receptacle: filaments like threads; anthers roundish, bursting inwardly. Style filiform; stigmas headed; capsules two, of two valves, hairy, one-seeded; seeds oblong and naked. This plant is met with in our stoves; is grown in sandy loam, and propagated by ripened cuttings.

*CURCULIGO* (Gaertner). A genus of tropical herbs, belonging to *Hexandria Monogynia*, and to the natural order *Hypoxidæe*. Generic character: flowers bundled, somewhat spiked, and bracteate. Corollas with tube slender, to which the styles are united, limb regularly six-parted, spreading; stamens fixed to the corolla; filaments slender, erect; anthers oblongly linear; style cylindrical; stigma a three-lobed head; berry longish. These plants thrive in loam and moor earth, and are increased by suckers, which rise from the root.

*CURCULIONIDÆ* (Leach). A very extensive family of coleopterous insects, belonging to the section *Tetramera*, and sub-section *Rhynchophora*, being generally known by the English name of weevils, and corresponding, for the most part, with the Linnaean genus *Curculio*. The frontal elongation of the head

into a snout, or rostrum, at once enables us to distinguish them from all other beetles. The *Bruchidæ*, it is true, have this part of the body produced in front, but it is very short in these insects, and cannot indeed be called a rostrum; moreover, the parts of the mouth are very distinct in the *Bruchidæ*, and their antennæ are filiform, or thickened; whereas, in the weevils, the mouth is exceedingly minute, and placed at the extremity of the rostrum, with the palpi scarcely visible, and of a conical form. From some of the wood-boring insects (*Xylophaga*, *Bostrichidæ*, and especially *Scolytus*), the less cylindrical form of the body, and the greater elongation of the rostrum, will serve to distinguish the curculionidæ.

When we consider "what dire events from trifling causes spring," and find the truth of this line confirmed in a thousand different ways by the agency of the minute objects of the creation, we may perhaps be not greatly surprised that the weevils (although furnished with a mouth, the various organs of which are so exceedingly minute, as to be apparently incapable of causing much detriment) are amongst the greatest enemies to the vegetable stores of mankind found amongst insects. Hence, there are no species so interesting in their economy, and so well worthy of being investigated in their different states, as some of those under consideration, since it is evident that it can only be by a positive acquaintance with the various times and places in which these creatures pass through their various states that we can ever hope to arrive at certain remedies against their attacks. We have already, in our article *CALANDRA*, given an account of the ravages of one of the most destructive insects in the family, viz., the corn weevil, and shall not therefore, in the present instance, enter further into the details of the habits of that particular group.

The great extent of this family, together with the minuteness of many of the species, render it very difficult to arrive at a knowledge of the various individuals of which it is composed. In the former respect, this group offers another curious instance of the great increase in our knowledge of the insect world, in addition to those which we have mentioned in former articles. At the beginning of the present century, Latreille stated that the family contained 800 or 900 species; Dejean, in 1821, gave 1073; and Schenherr, in 1833, 3544; since which many others have been discovered; so that, in twelve years, the number of species has been more than tripled.

The European species of this family are, for the most part, of small size. Amongst these may be mentioned the genus *APION* (which see); but the Indian and Brazilian species not only acquire a very considerable size, but are adorned with the most splendid colours. The diamond beetle (*Entimus imperialis*) may be cited as the best known example. This insect is of very common occurrence in the country which it inhabits, and is brought to Europe in great numbers; but opticians and others, who prize it for its splendid appearance, often demand high prices for large specimens. We have observed, that the most brilliant mode of examining this insect is to hold it near a candle, the light being between it and the eye, and then look at it with a lens of about three or four inch focus, when the effect is inconceivably rich and metallic.

The insects of this family are found in all climes; but the same cause which induces an increase of size

in the tropical species, operates also in producing a much greater extent in the number of species. This cause is found in the nature of the vegetation of those regions where, from its continued growth and vast luxuriance, the herbivorous insects are more numerous called into existence to support the regular operations of nature.

Many of these insects are also singularly formed, and of very varied colours; the latter character is, however, of a transient nature, depending on the presence of minute scales or powder, with which the body is covered. Of these, very common examples may be observed in the splendid little green species found so abundantly in the spring on the nettles. The slightest touch, however, removes these beautiful ornaments; so that, unless the entomologist secures them soon after their appearance in their beetle form, all their beauty will have vanished. Hence it has been fancifully said that the curculionidæ are the lepidoptera of scale-winged insects. Like the lepidoptera, also, their rostrum is tubular, elongated, and capable of being placed in a groove or cavity for its reception on the underside of the front of the body. The larvæ of both also feed on vegetables, and these larvæ in both are of a totally different form from that of the perfect insects, so that we may regard this as an instance of one of those curious rules which seem to exist throughout the animated kingdom, which Latreille thus stated more than thirty years ago—"Nature, in general, has a certain number of models which she re-exhibits ('reproduit'), with certain modifications, in all the classes, and even in the different orders of beings." This principle, which some of our leading naturalists of the present day have held forth, at very great length, as a novel idea, is certainly an interesting mode of viewing nature, even should we not feel inclined to regard it as entitled to so much weight in regulating our classifications of the animal kingdom as some of these authors have been induced to give to it. We will, however, defer to some more convenient opportunity our observations upon the nature of those affinities and analogies which unquestionably exist throughout nature.

In their habits, the curculionidæ exhibit all the symptoms of natural weakness. Of all beetles, they are provided with the least available means of defence, and are consequently the most fearful, avoiding both the light and noise; even the diurnal species are generally to be seen in a state of inactivity, their colours, resembling those of the substances upon which they are often found, also favouring their security. Unlike the majority of insects, if they are attempted to be seized, instead of unfolding their wings and flying away, they merely fold up their legs and antennæ, counterfeiting death, and falling to the ground. A few of the smallest species (forming the genus *Orchestes*) are more active, the large size of their hind legs enabling them to escape, by leaping to a very considerable distance, in a manner similar to that of the turnip beetle, and other species of the genus *Haltica*.

It is not often that these insects make use of their wings; indeed, many of the species are destitute of these organs, their wing-covers being in such cases soldered together. They also creep but slowly, but the underside of their tarsi is furnished with a kind of cushion, enabling them to retain their hold upon different objects in all positions.

It is in the larva state that the curculionidæ are the

most obnoxious to mankind; in the perfect state they can take but little food, and their chief care is, then, the propagation of their race. Their larvæ, like those of the *Cerambycidae*, are fleshy, with their legs rudimental, or entirely wanting; but those of the *Curculionidæ* have the body more or less cylindric, with the extremities somewhat narrowed, so as slightly to resemble a spindle. The head is horny, and furnished with a pair of powerful jaws, and other organs of a fleshy nature. The nutriment taken by these larvæ is very diversified, those whose organs of nutrition are most robust attacking the harder parts of vegetables; thus the larva, which is termed the palmiste, being the immature state of *Calandra palmarum*, gnaws the trunk of the palms. Other larvæ, whose mouths are less powerfully constructed, feed upon the farinaceous matter of various seeds, or the pith of various plants, while others devour the leaves and flowers. A few of the more minute sorts are miners, eating only the parenchyma of leaves. And here we may mention a circumstance, tending to show the incorrectness of the opinion, that those species of insects which feed upon imported plants are not indigenous to this country. The hollyhocks in our garden have, for several years, been much injured by the small grubs of one of these insects, which we have ascertained, by rearing them, to produce the *Apion radiolum*, a species ordinarily nourished upon the mallow, but which, in this instance, has preferred the hollyhock, probably from its larger size, although mallows were growing within a very short distance from the hollyhocks. The instinct of the parent insect induces her to deposit her eggs in such situations that the larvæ, as soon as hatched, find themselves in the midst of their natural food.

We must refer to our articles upon *APION*, *BALANINUS*, *CALANDRA*, and other genera, for additional observations upon the natural history of these insects.

The beautiful *Rhynchites Bacchus* (termed by the French agriculturists *La bêche*) does great injury in the vineyards, appearing in June, and devouring the young and tender shoots, extracting the sap by means of its long tubular proboscis. This causes the leaves to roll and shrivel up, and in the midst of these rolled-up leaves, surrounded by a silken covering, the eggs are deposited, from which are produced the larvæ, which also devour the leaves. An ingenious mode of destroying these insects has been adopted in France, which we think might be employed with much success in our own country in killing various obnoxious insects, especially those which attack trained plants. The insect, when disturbed, adopts the general mode of defence pursued by its tribe, folding up its legs, and falling to the earth, so that, by holding a small gutter of paper beneath the branch, and then shaking the latter, the insects, being at the time on the point of depositing their eggs, drop into the paper gutter, and are easily destroyed.

Another species of this family, *Lixus paraplecticus*, attacks the *Phellandrium aquaticum*, the larva boring into the stems; and it is asserted by some authors that horses, which feed upon the infected plants, are subject to a violent disease, which the Swedes term *stakra*.

The thistle, *Carduus spinosissimus*, nourishes another weevil, whose virtues were highly praised in past times as a specific against the toothach. This insect, accordingly, acquired the name of *Curculio antidontalgicus*.

and it was said that, if fifteen larvæ of this species, or fifteen of the weevils, immediately after their arrival at the perfect state, were rubbed between the fingers till all the moisture was gone, these fingers would acquire the power of causing a cessation of pain, on touching the affected teeth, for a period of twelve months, notwithstanding all the washing which they might undergo. Truly, our forefathers were not a whit less gullible than their posterity of the present day. When full grown, many of these larvæ enclose themselves in cocoons of silk, which, in some species, closely resemble net-work, with open meshes.

The great Linnæan genus, *Curculio*, has been from time to time divided, by different authors, into various other generic groups, into the details of which it would scarcely be thought profitable were we to enter. This may be conceived, when it is stated that Schœnherr has increased their number to 288. We shall, therefore, content ourselves with giving a slight sketch of the distribution of the chief subdivisions into which the group is arranged, taking it in its extended limits, and embracing the *Attelabides*, *Brenthides*, and *Bruchides*, which, together, constitute the sub-section *Rhyncophora*.

1. Antennæ not elbowed at the extremity of the basal joint; rostrum without lateral gutters, for the reception of the basal joint of the antennæ (ORTHOCEERI).
  - \* Upper lip distinct; palpi filiform, or thickened at the tips.
    - a Antennæ thickened at the tips (*Anthrribides*).
    - b Antennæ filiform; rostrum broad (*Bruchides*).
  - \* \* Upper lip not visible; palpi short, conical.
    - a Antennæ filiform, with the last joint alone forming a mass (*Brenthides*).
    - b Antennæ, with the three or four last joints, forming a mass (*Attelabides*).
2. Antennæ elbowed at the extremity of the basal joint, which is generally received in a gutter at the sides of the rostrum (GONOCERI).
  - \* Rostrum short; antennæ inserted near its extremity (*Brachycerus*, *Curculio*, *Hypera*, *Liparus*, and a very great number of other generic divisions).
  - \* \* Rostrum long, with the antennæ inserted near the middle of this rostrum. This division nearly corresponds with the genera *Lixus*, *Rynchænus*, and *Calandra* of Fabricius, from which a great number of generic and sub-generic divisions have been detached.

CURRENT, is the *Ribes rubrum*, &c. of botanists. It is a native of Britain, and has been long cultivated in gardens, and no domesticated plant repays the care and trouble bestowed on it more than this. It is not only a most agreeable and wholesome table fruit, but its pulp and juice are convertible into many excellent conffections, and sparkling wine, little if at all inferior to many sorts manufactured from the grape itself.

The currant, like all its alliances, are usually and easily propagated by cuttings. These should be chosen from among the most healthy and moderate-sized shoots of the previous summer; not those rankly luxuriant ones which sometimes rise from the root, nor the slender, dangling growths of the top.

\* We have altered Latreille's arrangement, by bringing the *Attelabides* into connection with the *Gonoceri*, the interposition of the *Brenthides* not appearing to us to be so natural as that given above.

The regular form of the future tree depends much on the proper choice and preparation of the cuttings. They should be from twelve to fifteen inches in length, after the knobbed part of the base, and slender points are cut off. All the buds on the lower part of the cutting should be carefully pruned off, leaving only four or five at the top, and which are destined to form the first branches. The cutting thus prepared is dibbed firmly into the ground, about five or six inches deep, as will allow as much for a clear stem, surmounted by the branches, at a due height above the surface of the ground. The cuttings may be planted either in autumn or in early spring, at a foot distance from each other, and on a rather shady spot of rich soil. Here they will not fail to prosper, seldom miscarrying, except from extreme drought, or by insects which destroy the foliage and points of the shoots.

The young plants will require no care during the first summer, nor till they want pruning in the following winter. At this first pruning some little skill is necessary in using the knife, in order to get the tree into good form. If the cutting has produced five shoots, the centre one had better be entirely removed, the four remaining (or if there be only three) will be enough of principal branches whence other shoots will be produced to form a head. The most desirable form is that of a cup; the middle being vacant, and surrounded by the fruit-bearing branches at about nine inches apart from each other. This is to be understood of the tree when it has arrived at its required height; because this form is gradually attained by the assistance of the pruner, in the following manner:—The first shoots are at the first pruning cut down to one-third of their length; these in the following summer produce a number of other shoots, some of which are reserved to fill up and complete the form, and the rest are pruned down to about an inch, to serve henceforth as a fruit-bearing spur. Thus the tree becomes annually enlarged till it has arrived at its full size, by which time all the primary and secondary branches will be also furnished with spurs.

These spurs yield the fruit and also a birth of shoots every year, which latter are spurred down at the winter pruning. This treatment is, or may be continued for half a score of years, if necessary; only occasionally cutting away old or worn-out branches, and training up young ones in their places.

But there is another way of pruning currant-trees which may be described in a few words:—no spurs are allowed to remain on the old branches, but instead of them a select number of summer shoots are reserved; and which, in consequence of their fewness, grow strongly. These at the winter pruning are reduced only one-third of their length; and the fruit produced from these shoots are invariably larger and finer than those produced from spurs. This last-mentioned method of pruning is eligible where quality is chiefly regarded; and the spurring mode where quantity is the object.

It has been a question whether or not it be expedient to divest the trees of their summer shoots while the fruit is swelling. Those who practise this process assert, that it assists to enlarge both the bunches, and berries, and also, by admitting the sun's rays, heightens the flavour. This is quite feasible, as the same thing is practised on the grape-vine; but a partial application of the knife in this case is always productive of the best results.

The best varieties of the currant are the large Dutch

white, the common white, large red, long-clustered red, the large Champagne, and the white crystal. They all delight in rich loamy soil; but will succeed any where if the ground be deep, moderately manured, and somewhat sheltered.

The black currant is a distinct species, and also a native of Britain. It is cultivated and increased by cuttings, as are the foregoing; but the method of pruning is somewhat different. Young plants are permitted to throw out ten or twelve branches from the top of the stem: these are allowed to rise to the height of three or four feet without cutting back. From the lower parts of these many shoots are produced annually: these bear the fruit and only require thinning, none of the young shoots ever being topped. As a constant succession of fruit-bearing shoots rise from below, the topmost ones which have risen too high, are cut out to allow the lower shoots room, and by this means the tree acquires its due form and requisite height.

All the currants may be trained to walls or as espaliers: in which situations they are most conveniently covered from birds and insects, and preserved for table a month or two after the regular season of such fruit.

CURRUC A (Auctorum), Warbler. A genus of small fruit-eating and insectivorous birds, belonging to the *Dentirostral* order, and *Sylviadae*, or pettychaps family, and of which the common blackcap (already described in its alphabetical situation) may be cited as a typical example. The bill, in the more characteristic species, is rather stoutish, at least for birds of this family, and is somewhat compressed; the gape almost smooth; the nostrils basal, lateral, oval, and exposed; wings with the first quill-feather very short, the second inferior to the fifth, and the third and fourth generally the longest; legs having the tarsi longer than the middle toe; toes short, and formed for perching; hind toe strong; the sole dilated and broad; claws much curved, grooved at the sides, and very sharp, that upon the hind toe strongest, and of greatest length.

This is one of the numerous and very distinct natural divisions which were formerly brought together and included in the immense Linnæan genus *Motacilla*, a huge and incongruous division, which was first reduced by Dr. Latham, who restricted that term to the wagtails, properly so called, but who again confounded, in his most comprehensive genus *Sylvia*, every small bird of a certain size which agreed in possessing a comparatively small and slender bill, however in other respects dissimilar. That designation also, in its turn, has now been limited to a particular group, the members of which exhibit some degree of resemblance in all their characters, and which therefore forms a most natural division; and the nightingales, the wheatear, the redstarts, the accentors, the aquatic warblers, wrens, goldcrests, and a host of others equally dissimilar (including the present group), all of which were formerly arranged together under the one name *Sylvia*, are now distributed into various independent genera, each known by a separate name, and distinguishable by well-marked and obvious characters.

There are three principal divisions of European warblers, that is to say, of small, soft-billed, mostly migratory, insectivorous birds, which chiefly seek their food about the foliage of trees and bushes; for the term *warbler*, as usually and technically applied in

works on natural history, has little or no reference to the vocal powers of these birds, a few species which excel in song having imparted this name to the whole group of which they are members. If we set aside, in the first place, the different wagtails and pipits; secondly, the robin and wheatear tribe; and thirdly, the different titmice and allied genera, each of which forms a very natural sub-family of the *Sylvianæ*, we have still, apart from the flycatchers and other tribes which usually take their insect food upon the wing, three leading subdivisions of small, migratory, arboreal, and insectivorous European birds, each of which contains a considerable number of species, and which, together, constitute what is called the *Sylviadae*, or typical sub-family of the *Sylviadae*. The first of them, comprising what are commonly called the different "willow-wrens," a number of little delicate birds with green plumage, and peculiar in their form and characters, will be fully described in the article *SYLVIA*; the members of the second, which are inhabitants of aquatic situations, breeding among the reeds, willows, and sedges, and which are in other respects very different from the rest, will be mentioned under the generic head *SALICARIA*; and the third, the *Sylvan*, or fruit-eating warblers, as they are appositely termed, a most natural group, now generally recognised under the name *CURRUC A*, are the birds we are now about to speak of. These three generic divisions, with one or two exceptions only, comprise the whole of the European species, which, in books on natural history, are usually denominated "warblers." We would restrict the term altogether to the last mentioned genus.

The most typical of the fruit-eating warblers are inhabitants chiefly of woods and thickets, orchards and gardens, some of which are less so, however, being found more along the hedges. They are all songsters, and most of them warble for a long time continuously, raising their voice as they proceed, and some of them invariably terminate with a loud and liquid flow of pleasing melody. They are mostly migratory birds, some of them being found in summer as far north as Lapland; but none are known to occur in winter, even in the most southern of the European countries, except as stragglers; a few of them, however, in the north of Africa, are more stationary. They feed upon various insects (more or less, according to the species); and they are very expert at capturing the winged ones as they fly by, but they never dart after insects like flycatchers, following them upon the wing, though this is sometimes done by all the *Sylvianæ* and *Salicariæ*. The writer of this has kept all the British species in confinement, and when tame, and suffered to fly loose about a room where there were plenty of flies, of which they are all extremely fond, he has often had occasion to observe, that, however quick they were at catching all that flew within their reach, they had not the slightest notion of following them into the air, as a willow-wren or redstart would have done. They invariably refuse earth-worms, and many sorts of caterpillars, but some they are extremely fond of; this, however, depends much upon the species, the garden warbler devouring several which are rejected by the whitethroat, and *vice versa*. In autumn they subsist more upon fruit, and various berries, of which they are very great devourers; some of them, indeed, feeding on little else during their whole stay with us, ivy and privet berries, and the like, supplying the

place of garden fruit during the spring. They all frequently erect the feathers upon the crown of the head and throat, and whilst doing so, not unusually emit a sort of *check*, or *tchut*, which varies a little in the different species, and much resembles the sound produced by tapping two pebbles together. This note must be familiar to most persons residing in the country. It sometimes indicates suspicion, or fear, as it is uttered whenever they espy an enemy, but is also expressive of various other emotions. They are mostly shy and hiding in their habits, concealing themselves amidst the thickest foliage. Their colours are chaste and unobtrusive, and they would in general be very little noticed, were it not for the almost incessant warbling of the males. They chiefly nidificate in low bushes; the blackcap and the garden warbler, however, often build in a forked branch, at four or five feet from the ground, and the lesser whitethroat sometimes at the height of nine or ten feet, but all of them most commonly near the ground. The nest is of rather flimsy construction, but firmly put together, composed chiefly of the dry withered stems of catch-weed or goose-grass (*Galium aparine*), woven into a kind of basket-work; in some species always with a little green moss on the outside, and lined with fine dry grass and horse-hair, with the addition, in some species, of small fibrous roots.

There is not a more remarkable fact, nor one more indicative of the entire and absolute distinctness of our different small birds, than that every separate species invariably constructs its nest in a manner so peculiarly its own, that a practised eye would never mistake it for the nest of any other species; the materials, perhaps, may vary a little, according to the locality, though even this is seldom the case, and never in any very remarkable degree; yet the mode of construction is always so precisely similar in different individuals of the same species, that there is never much difficulty in identifying the nest of any one of them. Still, however, notwithstanding this distinctness, there is always a great generic similitude in the nests of different birds of the same natural genus, similar to that which obtains in the birds themselves; and the more the birds approximate, the more closely (as the term is) they are allied, so in the same ratio the more do their nests resemble; each, however, still preserving some peculiar distinctive characters by which it may be always known. Indeed, if we trace also the various intermediate links, which almost imperceptibly connect the most dissimilar forms together, we may almost always observe a regular gradation in the nests, similar and corresponding to that which prevails in the birds. The same gradation is likewise very often observable, even in the very notes and songs of birds, in the nature and disposition of their colours and markings, and in the colours and markings of their eggs. A practised ear will at once distinguish every separate species by its peculiar notes; as in the genus *Curruca*, the subject of the present article, those of all the different species of a natural genus may have a very strong generic similitude, yet each is always readily distinguishable from all the others. As we meet with no mule productions in a state of nature, no intermediate specimens, so we find no intermediate nests, nor hear intermediate notes; each preserves in every respect its specific characters. It will be conceded that the most remarkable generic resemblances are those of the nests; yet so truly does

this obtain, that, in many instances, both generic and specific divisions may almost as safely be deduced from an examination of these as from the study of the birds themselves. In the present instance we have not ventured to give a generic description of the nests of all the species of *Curruca*, although that of each separate species presents invariably certain marked peculiarities, by which it may always be at once distinguished from those of any of its congeners, however, on a superficial view, these may resemble it. A common species of *Curruca* in the south of England is

THE GARDEN WARBLER (*C. hortensis*), one of the most delightful songsters of this or any country, but which, notwithstanding, is most wonderfully little known to people in general. In size and form it very closely resembles the black-cap, indeed so much so, that an albino or white specimen of either could not very readily be distinguished. It is, however, somewhat shorter than that bird, and rather more thickly made; all over of an almost uniform olive-brown colour, rather paler about the throat, and inclining to white upon the belly, and usually having a dash of grey upon the sides of the neck. This is one of the latest of our summer migrants to arrive in spring, and also one of the first to depart, in this respect differing widely from the black-cap, which is always one of the first of the summer birds to make its appearance, and one of the very last to leave us; a difference, by the way, which is singularly enough observable in several migrant birds, that are nearly allied to each other. The garden warbler is never abundant in this country till the trees are in full leaf, but its presence is always soon announced by the delightful flow of soft and pleasing melody which it pours forth, often from the top of some tall pear-tree, or, if not in a garden, generally from amid the branches of an elm. Sometimes he commences with some low twittering notes, not much unlike the song of the swallow, and raising his voice by degrees, through a series of charming and most delightful flute-like modulations, he ends with the full rich whistle of the blackbird, but delivered in a more hurried cadence. He usually continues singing about three or four minutes, when he stops as if to take breath, and almost immediately commences again; deep, rich, and mellow, his lovely warble is heard nearly throughout the day, and occasionally even after sunset, singing nearly throughout the summer, and as the season advances often both beginning and ending with the same loud blackbird notes. As in all other birds, some individuals are much finer songsters than others.

The garden warbler does not appear to be quite so generally dispersed over the country as the blackcap, though it may be more so than is commonly supposed, as it is often confounded with that bird. It is certainly very abundant in many parts of the south of England, and particularly near the metropolis; and Mr. Selby states that it is found "throughout the greater part of Scotland, particularly where the wooded districts margin the lakes and rivers." Montagu traced it through the greater part of England. Both this species and the blackcap frequently commence singing a few seconds before they settle, as they fly from tree to tree, continuing their song uninterruptedly after they have alighted. Indeed, these two species resemble each other most closely in their general habits, and the history of the latter, as given in the article BLACKCAP, applies in almost every respect to that of the garden warbler. They are both great

devourers of fruit, which they prefer to insect food ; inasmuch that, in confinement, when they first begin to get a little tame, they will frequently descend from their perch to eat fruit from the hand, when a buzzing fly has no attraction for them. In some of the species, as the white-throat and babillard, the reverse is the case, as, though extremely fond of fruit, these will sooner come down to a fly. The garden warbler is, perhaps, a greater devourer of caterpillars than any of the others, and in confinement will eat seven or eight in succession, of the caterpillars of the large white cabbage butterfly (*Pontia brassicæ*), which the others will not even touch. Its most favourite fruit seems to be the Kentish cherry.

Allied to this bird and the blackcap (*C. atricapilla*), there are several continental species, most of which have the outer tail feathers white. One of these, the *C. sarda*, chiefly inhabiting Italy and Spain, is said to be a charming songster. Another, the *C. melanocephala*, has very little melody to boast of. The *C. Ruppellii* is a beautiful species, the male of which has the head and throat black, divided by a white line ; this chiefly inhabits Barbary, and occurs, but only as a straggler, in the south of Europe. Further south we have the *C. Heinekia*, which, with the common *C. atricapilla*, is resident throughout the year in Madeira, and is said to be a fine songster. The *C. nisoria* is a European species, remarkable for its curiously spotted plumage ; and the *C. orphea*, an inhabitant of the south of France, is a very pleasing songster, resembling in its habits the common whitethroat ; this bird also has the crown of the head black, and is remarkable for generally nesting in society. The two last-mentioned species are of larger size than the rest.

An account of the babillard or lesser whitethroat (*C. garrula*) has been given in its alphabetical situation (see BABILLARD) ; closely allied to it are the *C. passerina* and *C. leucopigon*, both European birds. These three are of smaller size, and more restlessly active than the others. Their habits are intermediate between those of the blackcap and whitethroat. The last-mentioned bird (*C. cinerea*) is exceedingly common throughout the British islands, arriving in the southern counties about the middle of April, and frequenting hedgerows and commons that are covered with furze or brushwood. It is more a bush bird than any of the others, and frequently rises singing a little away into the air, a habit which is peculiar to it and perhaps the spectacle whitethroat (*C. conspicillata*), a smaller but very nearly allied Italian species. These too have the bill shaped somewhat differently from the typical or blackcap form, approaching more to a miniature of that of the blackbird ; in this, and in the habit of singing upon the wing, approaching to the Dartford warbler or furze wren, a species we shall presently describe, and which belongs to a separate subgenus. The whitethroat is an extremely lively and active little bird, almost perpetually singing, and ever erecting the feathers upon the throat and crown of the head, together with the tail, which gives it a characteristic appearance. The adult male has the irides yellow, the crown and region of the eyes dark grey ; the whole upper parts reddish brown, tinged with grey ; and the wing coverts and tertials broadly margined with mahogany. The throat is white, and the breast faintly tinged with rose colour, the latter hue being wanting in the female, which all over inclines more to reddish brown ; tail rather long, the exterior feather being a little shorter than the

rest, and having its outer web and tip white. All the birds of this genus may be readily known, as soon as hatched, from the other tribes of warblers, by their having the inside of the mouth and gape invariably red ; they leave the nest before they are half fledged, and skulk about the bushes, being only for a short time fed by the parents, who very soon commence again the work of nidification, and commonly rear three broods in a summer. The whitethroat, like the rest of the genus, frequents gardens and orchards in the fruit season, being a great devourer of cherries, currants, and the other smaller fruits. It appears to be a very long-lived bird ; for Mr. Sweet kept one in confinement for fifteen or sixteen years, at the end of which time it is described to be as active and lively as at first, to sing as merrily, and to show no sign of old age. They are very tame and familiar, and rather a hardy bird in confinement, and very amusing from their liveliness, singing with great spirit and energy against any other bird ; but, like the rest of the genus, they are very subject to a partial loss of feather during the winter. This species is exceedingly abundant upon open commons and furze-brakes, where its habits closely resemble those of the

FURZE WREN or DARTFORD WARBLER, as it is generally but not very appropriately called (*C. meliophilus provincialis*). This species was separated from the others by Dr. Leach ; it is of small size, with a bill like that of the whitethroat, but longer in proportion ; the tarsi also are rather longer than in the typical *Curruca*, the tail is much elongated, and the wings are short and rounded ; in all which respects it approximates to the genus *Malurus*, an African group of warblers ; it does not, however, construct a domed nest like those birds, but in its nidification and eggs closely resembles the whitethroat and other currucæ.

This curious little bird was first discovered in England, near Dartford, in Kent, whence it has been usually denominated the Dartford warbler. It is rare however in that neighbourhood, although generally speaking, wherever it is found, it occurs in abundance. It is plentiful enough upon some of the commons in the southern counties, inhabiting only the very thickest furzes, where its habits are so very shy and hiding that a person might traverse for months various situations where it literally abounds, without being once aware of its presence. It has consequently been usually considered a very rare bird, though it certainly is an extremely local one. Perhaps it is no where more abundant than in the adjoining districts of Surrey and Sussex.

This bird is a little larger than the common wren, but much longer including the tail, its total length being about five inches and a half, of which the tail measures almost half. Its weight is about two drachms and a half. The eyelids are yellow, inclining to orange ; irides reddish yellow, whence in Sussex they are provincially called "Red-eyes." The bill almost black ; base of the upper mandible whitish. The whole upper parts dusky brown ; cheeks dark ash colour ; two outer tail feathers tipped, and the outer one also edged with white. The throat, neck, and breast, dark cochineal red, inclining to purplish red ; in the young of the year, the feathers of these parts have each a fine streak of white. Legs and toes yellowish brown. This bird, when flying, has a very dark appearance, seeming to be almost black. It differs from the other species in being resident in this

country throughout the year; and, perhaps, the best time to see it is upon a fine frosty morning, at which time it appears extremely active and lively; it is constantly in motion; erecting the crest and tail, and uttering a low note, resembling *cha, cha, cha*; it also sings prettily, sitting on the topmost branches of the furze, but the song wants variety, being always the very same over and over again. Sometimes it mounts singing a little way into the air, or suspends itself over the furze; but at the least alarm it will descend into the covert, and it will be a long time before you can get another sight of it. It trusts entirely to concealment for protection, threading the intricacies of the thickest bush with great rapidity; and if in a solitary detached bush, you may knock about for ever without bringing it out; it will sooner suffer itself to be taken by the hand. Both nest and eggs of this bird are very like those of the whitethroat, and the young quit the nest in the same manner, before they are half fledged: at this time the artifices of the parents to draw an intruder off are very amusing; they make the same harsh sound as the whitethroat, and will almost suffer the hand to touch them, and then, perhaps, will fall from the spray, and tumble along the ground, as if fluttering in the last struggle for existence.

In confinement its habits resemble those of the whitethroat and its congeners, and it feeds on the same food; this it will frequently take while suspended to the wires with its head downward. It will also sometimes climb along the wires, a habit which, among the British warblers, is peculiar to this species and the lesser whitethroat. Both these little birds, also, in the cage, frequently perform somersets in the air, throwing themselves over backward; and both of them, at times, will utter a singular sort of rattling note peculiar to themselves. The furze wren is found in some parts of Germany, and is very common in the south of France; from its abundance upon the commons in Provence, it has received the trivial name of *Provincialis*. Buffon was the first to describe it, which he did under the name of "*le Pitchou de Provence*."

**CURSORIUS**—Swift-foot, a genus belonging to the pressirostral division of *Echassiers*, or stilt-birds, of which the generic characters are as follow: bill slender, conical throughout, and with a moderate gape; wings very short, or of mean length, second quill the longest, the coverts as long as the quills; tarsi long and slender; toes three, all horned to the point, and without any web.

These birds form a sort of intermediate link between the ostriches and the plovers, they are birds of the deserts, shy and retired in their manners, and found only in the warm parts of the eastern continent; but one of the species, at least, is discursive over a great range of surface, and makes a dash into the southern parts of Europe, and even into England. They are, perhaps, the fleetest footed of birds; and, if they are not come upon by surprise, or in places which are new to them, and in which they get bewildered and entangled among bushes, they are out of the reach of fire-arms in no brief space, so that very few of them are found. Of their time and manner of nesting, number of young, and other points of their economy in their native wilds, we are altogether ignorant. Three species, at least, are known.

**CURSORIUS ISABELLICUS**—common Swift-foot. A native of the northern parts of Africa: Isabelle yellow, or reddish cream colour, on the upper part, white on the under; top of the head red; two black rays over each

eye, separated by a patch of white; wing coverts bordered with ash colour, quills black; bill black; legs ash colour, length between nine and ten inches.—Sometimes, but very rarely, straggles into England.

**CURSORIUS BICINCTUS**—two collared Swift-foot. Also a native of Africa. Upper part brownish ash, each feather margined with reddish white; middle coverts of the wings reddish, quills black; rump white, under parts reddish; a narrow black collar on the lower part of the neck, and a broader one on the breast; rather larger than the former.

**CURSORIUS ASIATICUS**—Coromandel Swift-foot. A native of India. Brown on the upper part; top of the head, back of the neck, and breast, maroon red; lower belly and quills black; coverts of the wings ash-coloured, with white tips, and a black spot near the tip; thighs and coverts, and feathers of the tail, also white; bill black; feet yellow. This species is rather the smallest of the three; but there is no great difference in size between any of them. The last two have not been seen in the west of Europe.

**CURTISIA** (Hortus Kewensis). This is a tree from the Cape of Good Hope, named in honour of W. Curtis, founder of the Botanical Magazine, and other works relative to plants. It belongs to the natural order *Celastrineæ*, is treated as a greenhouse plant, but had never flowered in this country before 1831; according to the late Mr. Sweet, at the Cape it is called the Hassagay Tree.

**CUSCUTA** (Linneus). This genus is one of the most curious vegetable parasites known. Two species are indigenous in Britain, and there are six or seven foreign species. It belongs to *Pentandria Digynia*, and to the natural order *Convolvulaceæ*. Generic character: calyx of four or five lobes. Corolla somewhat globular, persisting, four or five cleft, and having scales at the base: stamens growing to the tube of the corolla; capsule two-celled, opening at the base; cells two-seeded. The dodder, as it is called in England, rises from its seed like any other dicotyledonous plant, and is supported by its own roots until its stems can lay hold of some other plant. This it holds in a firm embrace, inserting small fibres or suckers into the bark of its supporter, whence it draws nourishment after its own roots are dead. The nurse often dies under the burthen and exhaustion caused by the parasite, which is not very nice in its choice of a foster parent; heath, furze, broom, or thistles are equally relished by the incumbent; and, if introduced into the greenhouse by accident, riots among the plants there as unceremoniously as if it were on its native common. The dodder is sometimes raised as a curiosity; seeds are sown in pots, and when the seedlings are strong enough, they are placed close to the side of some soft-wooded, worthless plant, which they soon lay hold of and cover, extending a considerable distance around, if not prevented. The plants flower abundantly, and some of the species are fragrant.

**CUSTARD APPLE**. (The fruit of a genus found in the East and West Indies, called *Anona* by Linneus, because so named by the inhabitants of the Island of Banda, where some of the species are found. Indeed these fruit-trees are cultivated in gardens all over India, on the continent as well as on the Islands in the Indian Sea. In value and quality the fruit may be compared to some of our common pears, but with a less firm pulp, so soft, indeed, as to be easily sucked out of the skin. The *Anona cherimolia*, a native of South America, is said to be a fruit of very

great excellence, and by some preferred to all others. The sour and sweet sops of the West Indies are the muriated and squamose fruited custard apples; and are found useful even in that region of fine fruit. Some of the species have fruited in our stoves; and no doubt were their culture more attended to, by working the plants, and allowing space for their roots and branches, the fruit may be brought to a considerable degree of perfection. These plants require a rich loamy soil, and are propagated by ripe cuttings struck in sand.

**CUTANEOUS SYSTEM**, comprehends the skin and its appendages, hair, wool, bristles, spines, horn, hoofs, feathers, shells, crusts, scales, and other analogous structures.

The skin is composed of three layers of integuments, viz., the *Epidermis*, or cuticle; the *Rete mucosum*, or mucous web; and the *Cutis vera*, or true skin.

The epidermis, or cuticle, which is the external layer, is a dense semi-transparent, partially elastic membrane, which is common to all animal and vegetable bodies. It is everywhere continuous in its course, being reflected inwards into the mouth, nostrils, windpipe, gullet, and other open passages. By Dr. Munro, it was traced down as far as the cardiac region (upper portion) of the stomach of a horse, and by many physiologists it is supposed to line the whole tract of the alimentary canal. It invests the roots, stems, leaves, and flowers of all plants, forming an external covering, which protects them from the action of fluids, and from the extraneous effluvia which are constantly floating in the atmosphere. In thickness and texture, both in animals and vegetables, it varies exceedingly. It is very thin in birds, and along the mesial abdominal line of fish. In some animals, however, as the elephant and rhinoceros, it is so thick and impenetrable, that it constitutes an armour of defence which resists the assault of arrows, swords, javelins, and even musket-balls. It is thinnest in the human body around the lips, at the tip of the tongue, and at the extremities of the fingers; hence the sense of touch is most exquisite in these parts. It is thickest in the palms of the hand and in the soles of the feet, where, from repeated pressure, it is often converted into a dense horny substance. This thickness, however, is not altogether the result of pressure; for, even in the new-born infant, the cuticle in the palms of the hands and the soles of the feet is thicker than in any other part of the body. Its thickness, in like manner, varies in different plants. In the leaves of the pearly aloe it is very thin and delicate; around the trunk of the plane-tree very thick and coarse. Although insensible, this integument is still to be regarded as a part of the living system, for it is constantly undergoing decay and renovation. From the human body it continually exfoliates in small scales, and in some persons in very large patches, especially after sickness, on account of the vessels, which may be regarded as the connecting link between it and the subjacent layer, having become debilitated. At certain seasons of the year some animals, as serpents and caterpillars, cast their skin in an entire sheath. It is the same with plants. From the birch and currant tree the cuticle peals off constantly in small scales; from the elm it is detached in large flakes. The connexion between the cuticle and the subjacent layer of skin is very close; it is, however, readily

separated by blisters and by heat. Alcohol also loosens it in many of the inferior animals, as may be observed by immersing worms in this liquid. When the cuticle of the blistered surface has been thus destroyed, it is very speedily renewed—more speedily, indeed, than any other tissue of the body.

The skin, being the outer covering of the body, and affording it a surface of protection, does not readily absorb extraneous matters; yet, when the epidermis or cuticle is removed, and the subjacent layer laid bare, then absorption takes place very rapidly; hence, in order that the operation of inoculation or vaccination shall take effect, the virus must be introduced below the cuticle. This has been a subject of some contention; for, although the cuticle does obviously permit the transudation of sensible perspiration, the pores through which it passes are certainly not perceptible. The fact of cuticular absorption (says Dr. Milligan, after reviewing the experiments of many philosophers) may be thus stated:—The cuticle has no absorbing orifices opening on its surface, and the substances supposed to be taken up by these really make their way into the body by the action of the absorbing vessels of the lungs and subjacent cutis vera; yet, from the imbibing faculty common to the cuticle with dead or unorganised matter, many substances may, by long maceration or external violence, find a passage through it without any laceration being visible. It may be proper, however, to observe, that pores running in a spiral direction have been discovered in the cuticle of the whale; and, arguing from analogy, it may perhaps be inferred that similar spiral pores exist in the human cuticle, although so minute as to escape demonstration. The eminent Amici has, by the aid of his powerful microscope, shown that oval orifices, or *stomata*, as they are called, exist in the cuticle of plants, especially of those which have a green colour. No such stomata have, however, been detected in aquatic plants; their use, it is presumed, is to exhale water and absorb air. There are many provisions in animals to preserve the cuticle in a healthy state, which consist principally in secretions of an oily or viscid nature. In fish and mollusca it is defended from the action of the water by a viscid or glutinous secretion, which is continually poured out on the surface. This secretion keeps the skin of whales soft and smooth, like oiled silk, and enables them and other aquatic animals to emerge from the water with the cuticle dry. It is in some cases glairy and adhesive, as in the common slug; or mucous and slippery, as in the common eel. The cuticle of animals is, in the living body, readily distended, as may be observed by its extension in tumours, or swellings of subjacent parts. It is, however, less elastic in plants. When overtight, it causes contraction of the stem, as may be often seen in the plum or cherry-tree; and when subjected to pressure from unnatural excrescences, it is frequently ruptured; so also, when the trunk of a tree, as the oak or the elm, has attained a certain size, the surrounding cuticle cracks, and the surface of the trunk becomes rugged.

Immediately below the cuticle, and intermediate between it and the cutis vera, is the second layer of the skin, which was supposed by Malpighi to be formed of a peculiar mucus, wherefore it was called the *RETE*, or *CORPUS MUCOSUM*. Other authors regard it as a vascular net-work; and M. Gall supposed that it consists of matter similar to the brown matter which

exists in the brain. It may be described as a thin extended pulpy layer. It is the seat of colour, being white in the European, copper-coloured in the American, and black in the negro. Haller, Camper, and Blumenbach, doubted its existence in very fair persons. It is certainly not seen distinctly excepting in the negro.

The different complexion or colour of mankind, in different regions of the globe, has, it is notorious, given rise to various opinions and speculations; by some, being referred to a difference in original organisation; by others, being ascribed to the influence of climate, food, and other secondary causes. That this rete mucosum is, however, really the seat of colour, there appears to be no doubt; and the following ingenious theory in explanation has been proposed by Blumenbach:—The human body, it is well known, throws off a vast quantity of carbonic acid; that is, carbon in combination with oxygen gas. He supposes, then, that this carbonic acid is in this mucous layer decomposed, the oxygen is set free, and the carbon or colouring matter deposited on the mucus, which combines with it. This decomposition is presumed to be determined by the intense light and heat of a tropical climate; those parts of the body, therefore, which are protected from the light and heat of the sun, are not so dark as those which are more exposed. The palms of the hand, and the soles of the feet, are not in the negro so black as the face, neck, and back of the hand. African ladies, who live in the shade, have a much paler complexion than those who are much occupied in the open fields. It is darker in some parts of the body than in others, as in the eyelids and arm-pits. According to Cuvier, the shell of molluscous animals, the crust of the lobster, and other crustacea, occupy the place of this layer. It also degenerates into the thick dense horny substance, which form the beaks and claws of birds, and the claws of other animals. Under the cuticle of plants, the corpus mucosum is also found, and is described as the cellular integument (*envelope cellulaire*).

It is very obvious, in mosses and ferns, and is in plants also the seat of colour, being green in young stems, and white in those which are colourless. Mirbel remarks, that leaves consist almost entirely of this substance, covered on each side with cuticle. The stems and branches of both annual and perennial plants are invested with it; but in woody parts it is dried up and re-produced continually, such parts only having that reproductive power. The old layers remain, are pushed outwards by the new ones, and form at length the rugged dry dead covering of the old trunks of trees. In the *Quercus suber*, a species of oak abounding in dry mountainous districts in the south of France, and in Spain, Portugal, Italy, and Barbary, this herbaceous envelope is remarkably thick, light, and porous, and constitutes what is well known as the cork of commerce, a substance which was well known to the Greeks and Romans, who used it as stoppers for vessels (Pliny, *Hist. Nat.*, lib. xvi. cap. 8.), although it was not extensively applied to this purpose until glass-bottles were introduced, which was generally done in the fifteenth century. In this part of the plant the principal changes of the sap take place, and an operation is effected which is of vast importance in the economy of nature. Already it has been stated, that the human body throws off continually a certain quantity of carbonic acid gas;

by the respiration alone about a pound of carbon is got rid of daily; mammalia, and inferior animals, likewise expire it; as do also plants when in the shade. This being a very noxious, indeed poisonous gas, it may reasonably be asked, how the atmosphere is purified from it, and the earth rendered fit for the abode of living beings? Herein the wisdom of creative Providence is beautifully illustrated. Carbonic acid is composed, it has been said, of carbon and oxygen; the carbon is the basis of vegetable bodies, the characteristic ingredient of all kinds of charcoal. When the sun shines upon a plant, its leaves absorb the carbonic acid from the atmosphere, and decompose it; and this takes place in the herbaceous envelope; here the oxygen is set free, and the carbon left to be appropriated to the basis of the plant. The vegetable creation, therefore, is constantly purifying the atmosphere, yielding for every volume of carbonic acid which it absorbs an equal volume of pure oxygen. Upon this principle, some have supposed that, in the beginning of the world, plants were created before animals, and gradually purified the atmosphere, so as to render it fit for their abode. Be this as it may, the provision is exceedingly interesting; and calculated to excite the admiration of every reflecting mind.

Underneath this mucous layer, or rete mucosum, is the cutis vera, or true skin, which exists in all animals; but is less distinct in mollusca and crustacea. In quadrupeds it appears to consist of solid fibres, which cross each other in every direction; in fish it seems an homogenous and continuous membrane. Over this integument, an infinite number of blood vessels, and the extremities of nerves are distributed; so that it is properly speaking, the seat of the sense of touch. It is provided also with a vast number of little eminences or papillæ, which were discovered by Malpighi in the foot of a pig, in each of which the extremity of a nerve is supposed to terminate. These papillæ are particularly conspicuous in the parts most appropriated to the sense of touch; as the tips of the fingers, the point of the tongue, and the lips. They are also well seen in the bills of aquatic birds, as the swan, goose, and duck, and doubtless enable these birds to find the food concealed in the mud. They are also larger upon the lips of fish; on the toes of birds which, like those of the parrot kind, use their feet as organs of prehension; and round the lips of the shrew, the mole, and animals that burrow under ground. The vessels of this true skin throw off the watery part of the blood in the form of insensible and sensible perspiration; the former escapes imperceptibly, the latter perceptibly. By some it is considered doubtful whether the vessels of insensible are the same as those of sensible perspiration; the fact that the dog perspires insensibly, but does not perceptibly, favours the idea of the two kinds of perspiration being dependent on a different set of vessels. The cutaneous perspiration serves several important purposes in the animal economy; it keeps the outer skin or cuticle moist and supple; it favours the exercise of taste and touch; and regulates by its evaporation the temperature of the body. The cutis vera is also supplied with a number of little organs called follicles, which secrete an unctuous and sometimes sebaceous matter, varying in consistence, odour, and other qualities in different animals, and which, as already premised, preserve the skin in a healthy state. The vessels also of the true skin secrete carbonic acid, which is discharged from the surface of

the body : so that, besides being the organ of touch, the function of the skin is vicarious with that of the lungs, serving to remove the superfluous carbon from the system. It serves the same purpose even with fish ; for Spallanzani and Provençal found that the skins of fish produced carbonic acid as well as their gills. Although in plants an epidermis or cuticle, and envelope analogous to the rete mucosum, is found to exist, they do not appear to possess any integument analogous to the cutis vera, which, in descending the scale of organisation, may be said to terminate with the crustacea. The skin then of animals is found to consist of these three layers, which, when chemically examined, are discovered to be composed almost entirely of gelatine, an animal principle which united with tannin, forms the remarkable substance leather. When the skins, therefore, of animals are macerated in bark, the tannin of the bark, uniting chemically with the gelatine of the skins, forms this compound, which is insoluble in water, resists putrefaction, and becomes hard and tough when dry.

The cutaneous system of animals and vegetables comprehends also, as already mentioned, the appendages to the skin ; such as hair, wool, horn, feathers, shells, &c. HAIR is common to all mammalia, whales not excepted ; it also occurs, mixed with feathers, round the head and neck of certain birds ; it is, however, absent in reptiles, fish, and mollusca, although found to exist in many annulose animals, and even zoophytes. Every individual hair may be described as consisting of a hollow tube proceeding from a root or bulb below the cuticle, and terminating in a very fine point. The bulb is of an ovoidal shape, and consists of an external and internal covering—the former being composed of condensed cellular tissue ; the latter being a simple membrane which lines the interior of the tube. The cuticle introduces itself into the bulb, and having become attached to the hair at its root, is reflected back again ; hence the hair holds firmly to the skin. The tube arising from the bulb is filled with a soft matter called the medulla or pith of the hair, which is the seat of a kind of imbibition whereby the colouring matter secreted by the vessels of the bulb is raised so as to give an uniform colour to each individual hair. The human hair is generally either black, brown, auburn, yellow, or red ; besides which a white variety characterises the race of people termed Albinos. When the vessels which secrete this colouring matter, and which also nourish the hair, become debilitated—or when the secretion is interrupted by any violent mental emotion, the hair turns grey, or becomes purely white. This happened, it is well known, to the unfortunate Louis XVI. of France, the night previous to his execution ;—also to Marie Antoinette, the queen of France, whose hair became white during the period of her journey from Varennes to Paris. It also occurred to the unhappy queen Mary ; and many other cases of a similar description are on record. Sometimes even after the hair has turned grey during a period of affliction, it will afterwards recover its natural colour—and this loss and recovery of colour has occurred to some persons in a very short space of time. Black hair has been generally considered significant of a vigorous constitution ; white, on the contrary, was called by Lord Bacon the “colour of defect,” and is regarded as a sign of debility. Hence, horses with white feet, are thought to be more tender and susceptible of disease than those of a more uniform dark colour. When the ves-

sels which nourish the roots of the hair become debilitated, as in extreme old age or after sickness, the bulb collapses, its attachment to the skin is destroyed, and the hair is shed. This sometimes occurs irregularly and in patches : sometimes the disease is universal, and not a hair remains on the surface of the body. This occurred to the chevalier D'Eperney, who, after four months' studious application, and without any illness, lost his beard, eyebrows, eyelashes, and all the hair of his head and body. Certain kinds of diet, especially a fish diet, is said to produce baldness. In the Shetland islands, so common was baldness formerly, that it was a common saying that “there was not a hair between them and heaven.” Tournefort relates, that in the island of Mycene the inhabitants seldom arrive at the age of twenty-one without becoming so. There are some races of people that have little or no hair on the surface of the body. The Mongolian, Chinese, and American have little or none upon the chin or chest. Hair varies considerably in shape, texture, and in all its mechanical properties. Instead of being cylindrical, it is sometimes flattened, striated, and deeply grooved, or even beaded. It also varies much in length, firmness, tenacity, and disposition to curl ; all which varieties depend on some corresponding difference in the relative action of the vessels at the bulb or root. The human hair which is most esteemed in commerce, is about twenty-five inches in length ; and the more it falls short of this, the less value it bears. Its length and quantity is, in all animals, much influenced by change of season and climate. Previous to winter, the hair increases in length and quantity, and this increase bears a ratio with the temperature ; hence cattle and horses in farms near the level of the sea, have a shorter and thinner hair than those in higher elevations, where the temperature of the air is lower. The fur of animals, which is sought as an article of commerce, is thin, and would be less valuable if obtained during the summer than during the winter season. The influence of climate is still more obvious. The dogs of Guinea, and African and Indian sheep, possess so little hair on the body, that they may be almost said to be naked ;—the Siberian dog and Iceland sheep are, however, protected by a very long and thick covering. The fleece of sheep in England is entirely wool ; the Zetland and Iceland sheep, however, in addition to wool, have intermixed with it a quantity of coarse and shaggy hair. In warm countries the elephant and rhinoceros have scarce any hair ; on the contrary, the carcasses of those discovered in the ice of Siberia, are found covered with a sort of wool mixed with long thick hair, very similar to the coat of the Iceland sheep. To accommodate themselves to this change of season and climate, animals cast and renew their hair, just as birds moult, or as serpents and caterpillars cast their skin. Moles cast their winter clothing generally before the end of June. The fleece of sheep, if allowed to fall, is generally cast before the end of July.

In some cases the nerves which supply the roots of the hair serve to extend the sense of touch ; thus the hairs which form the whiskers of the lion, tiger, and cat, being supplied with pretty large nerves at their roots, the slightest impression is communicated from their joint to their base. It is the same with the whiskers of the seal. The hairs of the whiskers are moved freely at the will or pleasure of these animals, which is not the case with the hairs of the rest of the body, although under certain vio-

lent emotions, fear, fright, or anger, they are observed to become erect. This is caused by a muscular web, which lies below the skin, and is called the *panniculus carnosus*, the fibres of which in contracting force the hair into an erect position. It is well seen in dogs and cats. It commands, also, the erection of the quills of the porcupine, and the spines of the hedgehog. The colour of the hair of many quadrupeds, like the plumage of birds, changes at certain seasons of the year. The summer dress of the Alpine hare (*Lepus variabilis*) is of a tawny grey colour; as winter approaches, it gradually changes until it becomes snow white. The ermine, which frequents the outskirts of woods and thickets during summer, is of a pale reddish brown colour; in August it becomes clouded with pale yellow, and in November it is snow white. As spring returns the white becomes mottled with brown spots, and in the month of May its summer garb is resumed. The hair even of the human body is somewhat lighter in winter than in summer.

Wool is a cutaneous appendage which differs in no respect chemically from hair; it is, indeed, generally described as hair short and crisped. It differs, however, from hair, in being finer in texture and in growing more uniformly. Each filament of wool grows at equal distances, and if not shorn, all the filaments separate nearly at the same time from the skin, for the wool completes its growth in twelve months, and is then shed. Another peculiarity is the different degree of thickness which prevails in the wool on various parts of the same animal, besides the filaments are closer at their extremities or points than at their roots. Furthermore, the fleece which grows during winter is of much finer quality than that which is produced during summer. The physical qualities, however, of wool, are considerably affected by the soil on which sheep feed. It has been shown by Mr. Bakewell that the herbage of each district derives from the difference of soil peculiar properties, which when taken as food, have the power of affecting that process of the animal economy by which wool is produced. Accordingly, the wool of sheep pastured on chalk districts, or light calcareous soils, is hard and harsh to the touch; the wool of those pastured on rich loamy argillaceous soils, is always distinguished by its softness. The soils most favourable to the soft quality are, first, the argillaceous, and next, the siliceous; the calcareous, whether limestone or chalk, produces wools of a contrary quality; so that in proportion as these earths preponderate in a loose state near the surface of different soils, their effect may be detected, whatever be the breed of sheep from which the wool is shorn. If the weather be fine, sheep in this country are shorn in the month of June, although some farmers delay the operation until July. The wool in the state first shorn is called fleece, and each fleece is usually separated into three sorts: 1, mother wool, or that of the back and neck; 2, the wool of the tails and legs; 3, that of the breast and under the belly. This classification corresponds with the Spanish method of sorting into *rafinos*, or prime; *finos*, or second best, and *terceras*, or inferior sort. Till within a few years, the finest wool was imported from Spain; but next to Spanish sheep, the English yield the finest wool that can be introduced into the market.

BRISTLES and SPINES are modifications of hair; in the former the hair is stiff, in the latter inflexible. The bristles growing upon the back of the hog and wild boar form a considerable article of commerce,

being extensively used by brushmakers, shoemakers, saddlers, &c. They are imported into this country from Russia; those of Ukraine being held in the highest estimation.

HORN is a substance analogous to hair, and has, indeed, been identified with it. When the horn of an ox is examined, it is found to consist of fibres which run parallel with each other from the root to the point of the horn, sweeping along the course of whatever curvature it may describe. Their disposition, however, varies. Instead of being straight and sweeping these fibres in the horn of the ram present a waved or undulated appearance. Hence the substance of horn appears to be made up of a conglomeration of hairs; but this is not always the case, for the horns of the camelopard and stag are truly osseous. It would appear, indeed, that horn differs from bone in this, that horn is composed principally of animal matter intermixed with very little phosphate of lime or other earthy matter, while bone consists principally of phosphate of lime with very little animal matter. The density and compactness, therefore, of the horn, depends on the quantity of earth or animal matter entering into its composition. The horn of the rhinoceros is purely a cartilaginous or horny substance; here the animal matter predominates; the horn of deer is purely osseous, in this case the earthy matter predominates. Horns are in most animals to be regarded as weapons of attack and defence; and as such they are instinctively used; hence young cattle are observed butting with their head months before their horns appear.

The manner in which the horn is developed is as follows: immediately below the skin, and over the frontal bone, two tubercles may be seen in the young calf. These gradually become more callous, and enlarge in size, shooting out conically. This growing horn consists of three parts, an external sheath or prolongation of the cuticle, a vascular investment, and an internal osseous substance. The vascular membrane has two different powers of production at each surface; the internal supplies the phosphate of lime; the external deposits layers of horny substance. When three years old, the horn is smooth and handsome; afterwards its annual growth is marked by a circle or wrinkle at the base; and, according to the number of these, the age of the animal may be determined. Horns, however, do not always grow from the frontal bone; in the rhinoceros they proceed from the nasal bone, and in many other animals they arise immediately over the ridge of the occipital bone. In some species, as the stag, the male only has horns; and, generally speaking, as in the case of the goat, where both male and female have horns, the female are smaller than those of the male. The horns, however, of the bull are shorter and denser than those of the cow. Between the size of the horn and bulk of the animal there is no correspondence; some small breeds of cattle have very large horns, while some good-sized cattle, as the Yorkshire-polled cattle, have no horns at all. Horns vary remarkably in shape and size. The horns of the goat are rough, angular, and bent retrally; those of the red deer are branched, round, and recurved. The roe possesses horns which are round and erect; the fallow deer horns palmed at the top. The length of the horn varies considerably. Cattle with long horns are said to excel in their hide, hair, and the quality of beef; those with short horns in the quantity of the beef, tallow, and

milk they yield. The antlers of the stag, after remaining nearly a year, are cast off and soon replaced. Immediately before this occurs the carotid artery is seen to throb, and all the vessels of the skin are turgid, the heat of the parts being much augmented. A tubercle is then observed below the skin, which gradually increases in size, as it becomes converted into bone. The cartilage being ossified, shoots upward in the form of a lengthened cylinder, which soon divides into branches. The skin being carried along with and investing the horn, forms what is called its *velvet coat*, but when fully formed, it shrivels and peels off, and the antler presents then a smooth and bare surface. The rapidity with which the vessels form the antler is remarkable; an antler weighing thirty pounds is sometimes completely formed in the space of fourteen days. After being fully developed, the vessels at the base continue to deposit additional osseous matter, which is called the *burr*. The accumulation of this substance at length encroaches on the arteries, and by diminishing their capacity for containing blood, gradually cuts off the supply of nourishment. The antler is then nourished only by its own internal vessels. These at length shrink and become obliterated, and the horn then adheres to the head only as a foreign body. In the mean time the absorbent vessels under the base of the horn, scoop a groove between the living and the dead matter, so that the antler, deprived of support, falls upon the slightest concussion. Thus are these graceful appendages to the figure of this animal annually cast and reproduced.

**BEAKS, NAILS, CLAWS, SPURS and HOOFS**, are of the same composition as horn, consisting principally of gelatine with only a trace of earthy matter. The horny substance of the beak differs from horn in its colour not being so fixed. The colour of the bills of many birds varies with the season, and changes also after death: the colour of the horns of cattle is permanent. Nails differ from horn only in not being tubular, but deposited in flat plates. They occur in the toes of quadrupeds, birds, reptiles, and pass into claws. Spurs occur chiefly in gallinaceous birds; they are softened by heat, and may be easily bent into particular shapes. Hoofs are peculiar to herbivorous animals, forming a solid base and protection to the foot.

**FEATHERS**, which are the characteristic appendages to the cutaneous system of birds, form a covering which not only protects them from the inclemencies of the weather, but which, when large, as in the wings and tail, serve as instruments of motion. The structure of a feather is exceedingly curious. Each feather consists of a tube or barrel, from which proceeds the shaft or stock, on each side of which are affixed barbs or flat filaments tapering to a point. The tube or barrel takes its rise like hair in the tissue immediately below the *cutis vera*, and passes by a tubular opening through the other layers of the skin, which are so folded downwards and inwards as to form a sheath, which invests the bulb or vascular part of the feather. The tube or barrel is a hollow, horny, transparent cylinder, consisting of two layers, an external and an internal. The external is a circular plate, exhibiting linear impressions which run round the barrel in a transverse direction; the internal consists of fibres running longitudinally. It is largest in anserine and gallinaceous birds, as the turkey, swan, goose, &c., for which reason the quills of these birds are best

adapted for making pens. By being formed into a hollow cylinder, the barrel of the feather is rendered stronger, lighter, and more capable of resisting flexion, than it otherwise would be. Its cavity indeed in some birds of flight, as the condor, eagle, and hawk, is continued some way into the shaft, and is, like the bones of the skeleton, filled with air, which enters into it during respiration through a minute orifice at the extreme point or end of the quill. Within the barrel is a dry jointed membranous substance, which is the remains of the vascular pulp which originally contributed to the growth and nourishment of the feather. The shaft which is prolonged from the barrel consists of a cuticular layer, disposed likewise in a circular and longitudinal direction, the central portion of which is filled with a pithy substance like cork. Its outer surface is slightly convex, its inner nearly flat, with a groove running along the middle. From each side of the shaft proceed the barbs, which are placed with their flat sides towards each other, whereby a power of resistance is derived which enables them when flying to encounter the impulse and pressure of the atmosphere.

They derive this power of resistance, says Dr. Roget, from the flattened shape of these filaments, which allows them to bend less easily in the direction of their flat surfaces than in any other, in the same way that a slip of card cannot easily be bent by a force acting in its own plane, though it easily yields to one at right angles to it. Now it is exactly in the direction in which they do not bend that the filaments of the feather have to encounter the greater resistance and impulse of the air; it is here that strength is wanted, and it is here that strength has been bestowed. But this is not all: in birds of flight and water birds, the barbs are, by their adhesion to each other, rendered firm, and this is effected by a very curious mechanism. When viewed under the microscope, a number of minute fibrils or processes are seen arranged along the margin of the laminae, so curved as to interlace with or clasp one another whenever they are brought within a certain distance. Those fibrils which proceed along the side of the laminae in the direction from the quill and to the extremity of the feather are long, flexible, and bent downwards; those which proceed from the adjacent lamina, from the extremity of the feather towards the quill end, are shorter, firmer, and turn upwards, so that when the long fibrils are forced far enough over the short ones, their crooked parts fall into the cavity made by the crooked parts of the other, just as the latch that is fastened to a door enters into the cavity of the catch fixed to the door-post, and there hooking itself fastens the door. These little teeth, like processes or barbules, are wanting in feathers not intended for flight; hence they are not found in the feathers of the ostrich, nor do they interclasp each other in the manner above described in the feathers of the peacock's tail, nor in those placed around the ear of the owl. The feathers of nocturnal birds of prey have the barbs covered with long silky down, whence, it has been observed, arises the slow and silent flight of these birds.

The mode in which feathers grow or become developed has been attentively examined by several naturalists, especially by M. Cuvier, whose memoir in the *Mémoires du Muséum*, tom. xiii., comprehends almost all that is known on this intricate subject. On quitting the egg, the body of every bird is found covered, excepting the under part of the belly, with a sort

of down consisting of minute filaments collected in tufts, which are implanted in a bulb or follicle which contains the sheath of the feather. When the sheath protrudes through the skin it has the appearance of a thorn or little cone, within which may be observed the medulla or that central gelatinous cord which may be considered to form the different parts of the feather. Upon its protrusion the tufts just described generally fall off, excepting in the eagle, vulture, and other rapacious birds, to the feathers of which it remains attached for a considerable time resembling fine down. From the medulla or pith the barbs are first discovered proceeding from it in very delicate and thin filaments; then the shaft or stalk of the feather makes its appearance, to which they soon become attached; the whole being enclosed within the sheath, the barrel end of which is filled with a glairy fluid. In proportion as this fluid becomes converted into the barbs and shaft, the central cord withers and corrugates. The sheath is at length burst open, and the medulla appears encircled by the barbs and shaft. These parts being formed, the remaining part of the medulla becomes enveloped with the matter of the quill which is a continuation from the shaft. The quill therefore is the last part formed, and continues to increase in length for some time after the full growth of the barbs and shaft. When feathers have reached their full growth they become dry, and only the tuber or medulla within it continues to absorb moisture at its termination or bulb. It gradually, however, ceases to receive this nourishment; its attachment to the skin then becomes loosened; and the feather is cast, and again in the manner described renewed. This periodical change of plumage is termed moulting, during which period birds generally become sickly and much debilitated. Immediately below the feathers of aquatic birds, in the region especially of the chest, other small and very delicate feathers are found which are called down, which serves to protect the body from the action of the water, and which, not being good conductors of heat, likewise preserve the temperature of the body. The down of the eider duck is esteemed the most valuable. These birds pluck it from their breasts to line their nests with it. So elastic is it that a quantity weighing only three quarters of an ounce will spread over a larger surface than the crown of the greatest hat. That found in the nest, which is termed live down, is much more elastic than that plucked from the dead bird, and is more highly esteemed.

The colour of the plumage of birds varies exceedingly, being in many species, especially in tropical climates, of dazzling brilliancy. The iridescence of the plumage is referable to the same cause as the colours of very thin plates, which has been explained in the article COLOUR. It is, however, remarkable that the colour of the plumage of certain birds undergoes a change at different seasons of the year. Among aquatic birds, the black guillemot (*Uria Grylle*) is of a sooty black in summer, with a patch of white on each wing; as winter approaches, the black gradually disappears, until the plumage becomes white, mottled with ash-coloured spots. Again, the ptarmigan or mountain grouse (*Tetrao lagotis*) has an ash coloured plumage, which, however, changes in winter to a snow-white; a providential change, says Montagu, for, were the surface of the ground not consonant with their colour, few would escape the

searching eye of the falcon or the eagle in the lofty and exposed situations they are found to inhabit. It has therefore been wisely ordained that the young first appear, like their parents, in a mottled plumage, similar to the lichen-covered rocks they frequent, and continue in this dress till the approach of winter, when old and young become equally white as the surrounding snow. In the Scottish Highlands this change commences about the month of September; large patches of white appear on the feathers of the wings and back; these extend, and in the month of January the bird is of a pure white. The return of colour commences by the appearance of black spots, which enlarge; they become of a brownish hue, until the colour and the summer plumage is completely resumed. This change of colour is, however, sometimes limited to a certain part of the body. Thus the cheeks and throat of the little auk (*Alca alle*) are black in summer, and become of a dirty white in winter; the head of the black-headed gull (*Larus ridibundus*), as the name indicates, is black in winter, and becomes white in summer.

SHELLS and CRUSTS are a part of the cutaneous system of the crustacea, besides which they occur to several of the annelides, as the serpula and dentalium. They consist simply of layers of earthy matter interposed between membranes of animal matter. This deposition takes place between the epidermis or cuticle and the cutis vera or true skin. It occupies the place of the rete mucosum above described. Crusts differ from shells only in being more brittle, in consequence of being composed of a greater quantity of earthy matter. In shells the carbonate of lime predominates; in crusts there is also a considerable portion of phosphate of lime. The size, texture, shape, and colour of shells, display an infinite variety. The shield of the snail is semi-transparent and elastic, the shell of the volutes opaque and hard as marble. River shells are not so diversified in form and colour as land and sea shells; but so numerous and varied are the characters of shells, that their study and classification constitutes, under the term CONCHOLGY, a complete department of natural history.

The crusts of the crustacea like the hair of quadrupeds, or feathers of birds, are cast periodically, and when injured or destroyed are easily renewed. When this change occurs in the lobster, his shell grows soft, the sutures open, and the claws burst at the joints. Thus loosened, the animal, by a trembling motion, or sort of spasm casts off his case, and then retires in a state of nakedness to the hollow of rocks. The released body then makes a sudden growth, and in about eight and forty hours a fresh concretion of humour is deposited over the whole surface of the body, which soon hardens into a crust, which is adapted in every part to the increased size of the animal. This change takes place annually. Besides in the crustacea, properly so called, crusts occur in certain insects, echinodermata or sea urchins, and starfish.

Lastly. SCALES are the cutaneous appendages or covering proper to fish; they are found also in every part of the body of certain reptiles, and also upon the feet of birds. They are composed of the same matter as the cuticle which extends over them; and they vary considerably in size, form, colour, and relative position. Such are the appendages, which constitute a part of the cutaneous system of the different classes of animals which inhabit the earth, the air, and the waters; and which afford a protection adapted in the

best possible manner to their different and individual exigencies.

**CYAMUS** (Latreille). A genus of crustaceous animals belonging to the section *Edriophthalma* and order *Læm dipoda*, and having for its type a curious species, which is found upon the bodies of living whales, being the *Oniscus ceti* of Linnæus. This genus constitutes a distinct division in the order to which it belongs, to which Latreille has given the name of *Ovalia*, oval bodied, in order to distinguish it from the other division of which *CAPRELLA* (which see) is the type, and which is remarkable for the long and slender form of the body. These animals were considered by M. Savigny as being nearly allied to the *Pycnogonida*, and forming with them the passage between the crustacea and arachnida. The body is composed of a small somewhat oval-formed head and six transverse segments, the abdomen being very minute and rudimental. The head is furnished with two moderate sized and two minute antennæ, with an oral apparatus, concerning the various organs of which authors are somewhat at variance. At the base of each of the smaller antennæ is a small depressed cup-like spot covered with a membranous substance, and which has been regarded as the organ of the sense of hearing. The eyes are two in number and granulated, although Savigny calls them "yeux lissées," whilst the yeux composées, which he mentions between the antennæ, are not discernible. The legs, or the limbs representing those organs, are of varied form, the first pair being slender and terminated by a claw and a moveable finger, the second, fifth, sixth, and seventh pairs are greatly dilated and terminated by a large joint, and a moveable recurved finger; but the most curious portions of the animal are the organs representing the third and fourth pairs of legs, and which consist in two or four pairs of long and slender appendages, which have been considered to be organs of respiration; these are, moreover, furnished on the underside of the body of the females with four large plates serving as a pouch for the reception of the eggs.

We are indebted to M. Roussel de Vanzème (whose memoir upon another whale parasite, *Cetochilus australis*, we have in an article upon that genus noticed,) for the most complete account hitherto published of this curious group of parasites, and which were observed by him in his voyage to the whale fisheries in the Southern Ocean. Previous to the publication of his memoir in the *Annales des Sciences Naturelles* for May 1834, one species only had been described, although Latreille in the *Règne Animal* had mentioned the existence of two other species inhabiting the Indian seas and the ocean near the Cape of Good Hope. M. Roussel, however, not only distinctly described three species living upon the whales of the Southern Ocean, but also observed their respective habits.

Sometimes these creatures are so abundant upon the whales, that the infested animals can be easily recognised at a very considerable distance by the white colour which they impart to the whale, and which is visible when it rises to the surface. When these parasites are removed the surface of the body is found to be deprived of the epidermis, and as it were corroded. They are ovoviviparous, producing eggs which are received into and hatched within the pouch-like plates on the undersides of the centre of the body, at times eggs alone, at others both eggs and young, and at others young only being observable in

the pouch. *Cyamus ovalis* and *gracilis* are stationary, being found in great numbers agglomerated upon the corneous eminences of the *Balæna mysticetus*. *C. erraticus* is, however, organised for its wandering habits, being of a slender form and with stronger legs serving for prehension. The young ones appear with all the characters of their kind, only the head is rather large, and the supposed branchial appendages instead of being long and slender are short and somewhat globose; the females of *C. ovalis* cover their young with their bodies, whilst those of *C. erraticus* abandon their young conformably to their own mode of life; and in *C. gracilis* the females, males, and young are all found mingled together.

**CYANELLA** (Linnæus). A bulbous genus from the Cape of Good Hope. Linnæan class and order: *Hexandria Monogynia*, and natural order *Asphodelææ*. Generic character: corolla of six-spreading unequal petals, inner ones longest: stamens below the germen; filaments united on a fleshy cup at the base; anthers erect, five are equal, bursting at vertical pores; the sixth twice the size, and oblong. Style declining; capsule three-celled, three-valved, and many seeded. The flowers of this genus are of various colours, handsome and sweet-scented. The plants are kept in a pit or frame, or may be planted in front of a hothouse, where they will succeed if defended from frost.

**CYANITE**, a mineral which derives its name from a Greek word, indicative of its sky-blue colour. When pure, it is idio-electric, as some crystals by rubbing acquire negative electricity,—and others with a similar surface positive electricity: hence the name *dithene*, given by Haüy to this mineral on account of its double electrical powers. It occurs massive, and disseminated; and is sometimes regularly crystallised. The primitive figure is an oblique, four-sided prism. It is found in various parts of Europe, Asia, and America. The Shetland Islands produce some very beautiful specimens, and it is readily distinguished from actynolite by its cleavage and infusibility.

**CYANUS**. Is the *Centaurea cyanus* of botanists a common plant in corn-fields, provincially called blue-bottle.

**CYATHEA** (Smith). A West-India fern, of tree-like stature, and highly ornamental. It was described as a *Sphæropteris* by Bernhardt and Wallich, and *Peranema* by Don.

**CYBIUM**, a genus of spinous-finned fishes, belonging to the mackerel family, *SCOMBEROIDÆ*, which see.

**CYCADEÆ**,—the *Cycas* family. A natural order of dicotyledonous monochlamydeous plants, containing two genera, and nearly thirty known species. Much difference of opinion has existed among botanists as to the particular situation which this order ought to occupy in the natural system. By some it has been included in the monocotyledonous or endogenous class of vegetables. In so doing these authors have laboured under an obvious misapprehension as to the real structure of the cycadeæ. The order may be said to have a nearly equal relation to the flowering or flowerless plants; agreeing with the former in the presence of the sexes and the completeness of the vascular tissue, and with some of the latter, such as ferns, in the peculiar gyrate vernation of the leaves, and the imperfection of the spiral vessels. By Lindley, *Cycadeæ* are included along with *Coniferæ* under a section of vascular plants, to which he has applied

the name *Gymnospermæ*, and which are distinguished by the seeds being naked, and the vessels of the wood having large apparent perforations, to which nothing similar is seen elsewhere.

This order was by some botanists in former times included under the fern tribe, in consequence chiefly of the mode in which the leaves are developed. Linnæus originally considered it as belonging to the palm tribe, to which it appears at first sight to have an affinity in its large pinnated leaves, and simple cylindrical stem. It differs, however, totally from palms, in being dicotyledonous, and in having an essentially exogenous stem, a gyrate vernatim and naked seeds, which grow on the margin of a contracted leaf. The order to which *Cycadææ* bears the closest resemblance is *Coniferæ*, or the pine tribe. With this order it agrees in the structure of its seeds, the form of its inflorescence, the arrangement of the veins of the leaves, the imperfect development of spiral vessels, and the apparent perforation of the vessels of the wood.

The essential characters by which the order is distinguished and separated from all others are: Flowers naked, dioecious, terminal; sterile flowers monandrous, collected into cones, each floret consisting of a single scale or anther, bearing the pollen on its under surface in two-celled cases; fertile flowers, either collected into cones or surrounding the central bud in the form of contracted leaves without pinnæ, bearing the ovules on their margin; ovules solitary, naked, with no other pericarp or covering than the scales or contracted leaves upon which they are situated; seed with a horny integument; albumen fleshy, solid; embryo inverted, the radicle being next the apex of the seed, from which it hangs by a long stalk or funiculus with which it has an organic connection.

The plants belonging to the order are trees with a cylindrical undivided trunk, increasing by the development of a single terminal bud, and covered with the scaly bases of the leaves, which are pinnated, with a gyrate vernatim and parallel veins. They are natives of tropical regions, and are found in America and Asia. They also grow at the Cape of Good Hope, and in Madagascar. In general they possess mucilaginous properties.

The genera of the order are cycas and *Zamia*.

*Cycas circinalis*, broad-leaved cycas, is a native of the East Indies, especially the Molucca Islands, where it attains a height of fifteen or twenty feet. The tree is called *Indu* by the natives. Its trunk is covered with the scars whence the old leaves have fallen, and from the top of the stem grows a crown of most beautiful foliage. It bears a drupaceous, smooth, reddish, orange fruit about the size of a walnut. The outer pulpy portion is about half an inch thick, and surrounds the inner horny coat, which covers a beautiful membranaceous lining of a rich brown colour. The tree was introduced into Britain by the Earl of Clarendon in the year 1700. It is very ornamental in our green-houses, but requires much space for the full display of its leaves.

The fruit of the tree is used in India as an article of food. From the soft centre of the stem a farinaceous substance is procured in many respects similar to the sago obtained from the sago palm. In preparing this substance, the stem is cut into pieces, several feet long, which are afterwards split longitudinally, so as to expose the pith; this is taken out, mixed with cold water, and then beaten with a wooden

pestle in a large mortar or trough. The mixture, after being allowed to stand for some time, gradually deposits a sediment, which is easily separated by decantation. This substance which may be denominated spurious sago, is merely the starch contained in the pith.

The nuts after being dried for a month in the sun, are beaten in a mortar, so as to separate the kernels, which are afterwards made into a kind of flour: much used by poor people in India as a nutritious article of diet, and called by them *Indum podi*.

In some Catholic countries the leaves of this plant are carried in procession, and used to adorn temples on Palm Sunday, in place of those of the date palm.

*Cycas revoluta*, revolute-leaved cycas, is a native of China and Japan, where it attains the height of five or six feet. It produces leaves four or five feet in length, which crown the trunk and form a magnificent basin ten or twelve feet broad at the base. The tree produces an orange-coloured drupe, nearly as large as an apricot, containing much white transparent mucilage, and enclosing an oval-shaped nut. The fruit has a mealy sweetish taste, and is eaten by the Japanese.

From the pith of the young stem of this species also, a kind of sago is procured, which is highly esteemed in the countries where the tree grows.

The plant is cultivated in stoves in this country, into which it was introduced in 1799.

*Cycas uernis* is another species found wild in China, where it is also much cultivated for its beauty. Its trunk is five feet high, and it bears an egg-shaped fruit of a red colour. In Tonquin, a valuable sago is made from the pith.

The genus *Zamia*, resembles the last in many respects. It includes upwards of twenty species.

*Zamia spiralis*, yields large nuts, which are said to be eaten roasted by the natives of New South Wales. *Zamia cycadis*, bread-tree *Zamia*, is a native of Southern Africa. By the Caffres and Hottentots the pith of the tree after being buried in the earth for some time, is made into cakes which are used for food.

CYCHRUS (Fabricius). A genus of coleopterous insects belonging to the section *Pentamera* and family *Carabideæ*. These insects are of a moderate size, having the body robust and destitute of wings, the upper lip notched, the upper jaws long and rather slender, the maxillary and labial palpi with the last joint large and spoon shaped, the tarsi are alike in both sexes, and the body is much narrowed in front. They are generally of a black colour, and are found under the bark of decaying trees, and beneath moss and dry leaves lying at their roots, more especially in mountainous regions. They appear exclusively to inhabit Europe, Asiatic Russia, and North America. Dejean describes nine species, but there is only one indigenous to this country, namely, the *Rostratus* of Linnæus, a species having so much resemblance to some of the darkling beetles (*Melasma*) that Linnæus was misled as to its true relationship with the *Carabi*, and placed it in the genus *Tenebrio*. The robust structure of the mouth, however, and especially the great development of the palpi, prove that its habits are not less ravenous than the remainder of the family to which it belongs. It is found not uncommonly in the spring under dead leaves in the woods and commons near London, and is about three quarters of an inch long, and of a black colour, the elytra having a granulated appearance. It owes its specific name to

the front of the head being elongated into a kind of beak. Two other species, *C. elongatus* and *attenuatus*, have been mentioned as inhabitants of this country, but without sufficient authority.

CYCHLA, a genus of spinous-finned fishes, belonging to the family LABROIDEÆ, which see.

CYCLAMEN (Linnaeus). A genus of European tuberous rooted herbs, cultivated for the beauty of their flowers. The genus belongs to *Pentandria Monogynia*, and to the natural order *Primulaceæ*. Generic character: calyx bell-shaped, divided half way down into five parts; corolla base swollen, throat a little prominent, segments of the limb reflexed; stamens borne on small filaments inserted in the tube; anthers connivent and arrow-shaped; style filiform and protruding; seed-vessel a berry, but opening at last into five parts; seeds seated in the pulp. These plants were called sow-bread by the ancients, in allusion to the tubers being sought for and eaten by hogs. The Persian is the only greenhouse species, but all deserve to be kept in pots, and placed where they may be seen to most advantage. They yield abundance of seeds by which they are easily increased, provided the seed is sown soon as it is ripe.

CYCLAS (Lamarck), TELLINA (Linnaeus). This genus of molluscs has been separated from the genus *Tellina*, in consequence of certain well-defined distinction: these, nevertheless, though sufficient to separate them from that genus, have led to some speculation on the part of modern malacologists; and we find in the French school that the genus *Cyrena* of Lamarck, the genus *Cornea* and *Corbicula* of Megerle, and the *Galathea* of Cuvier, are all considered as subdivisions of the genus *Cyclas*; and though we do not advocate an useless multiplication of genera, we cannot altogether agree with that arrangement; however, as the general habits of these molluscs, as well as their organisation, nearly correspond, we give the following description in accordance to the French school:—The shells of this genus are small, of a very convex oval form; valves very thin, and always without three primary teeth on either of them; apices never eroded or decorticated; some species are so thin and fragile as to be transparent; the valves smooth or transversely striated; shell transverse, equivalve, apices protuberant; primary teeth very small, almost obsolete, sometimes two on each valve, of which one is plaited in the middle of the one valve, and sometimes two plaited or folded teeth on the other. These constitute Lamarck's genus *Cyclas*. Such species as have a suborbicular form, the cardinal teeth rather variable, and always very small, if not altogether obsolete, with the apices not eroded, form the genus *Cornea* of Megerle. The species of a subtrigonal, or an elongated oval shape, having the apices eroded, and more anterior, with three cardinal teeth, the two posterior of which are bifid, constitute Lamarck's genus *Cyrena*, and those having the lateral teeth dentated, but corresponding in other respects, form the genus *Corbicula* of Megerle. The species of a subtrigonal form, with two-grooved cardinal teeth on one valve, three on the other, the middle one being larger and callous, form Lamarck's genus, *Galathea*. All these molluscs inhabit fresh water, generally buried in the mud; the two last sections only are known in Europe: the greater number of the others being from the Indian rivers, but every part of the world presents species of the first division; the shells are generally provided with an epidermal coat. The

animal has its body of an oval form, the edges of the mantle plain, the tubes short and united, the foot large, compressed at its base, and terminated by a species of foot, or appendage answering that purpose. This genus is classed in the third class *Acephalophora*, third order *Lamellibranchiata*, eighth family *Conchacea*.

CYCLICA (Latreille). An extensive division of coleopterous insects belonging to the section *Tetramera*, distinguished by the generally short and rounded form of the body. They differ from the *Rhynchophora* or weevils, in not having the head produced into a rostrum; from the *Xylophaga*, by having the antennæ not clavate; from the *Platysoma*, by the body not being flattened; from the *Longicornes*, in the antennæ being shorter than the body; and from the *Eupoda*, in having the hinder part of the thorax as wide as the base of the elytra.

For the particular characters of this division as well as for an account of the families of which it is composed, we must refer to our article headed *CHRY-SOMELIDÆ*, where, in consequence of this division nearly corresponding with the Linnaean genus *Chrysomela*, we have thought it more convenient to give a description of this group.

CYCLOBRANCHIATA is the name given to an order of molluscs having the organs of respiration branchial, in the form of tufts, more or less developed, symmetrically arranged near the vent, which is situated in the median line of the posterior part of the animal's body. The skin is naked, though sometimes tuberculated. This order includes the genera *Doris*, *Onchidoria*, and *Peronia*; of the second class, *Paracephalophora*, they will be described in their respective places.

CYCLOPS (Muller). A genus of minute aquatic crustaceous animals, considered by M. Edwards as entitled to the rank of an order, to which he has given the name of *Copepoda*. These little creatures, which abound in fresh and standing waters, are seldom more than one-eighth of an inch long, and may constantly be observed jerking about by the assistance of their long tails. In their forms they somewhat resemble a lobster in miniature, the thoracic part of the body being of an oval form, furnished with a single eye in front (whence the generic name of the group). This part of the body is divided at its hinder part into several segments, which are succeeded by an articulated tail or abdomen, from the base of which in the females depends on each side a large membranous bag containing the eggs. The abdomen is forked at its extremity, each division being furnished with strong setæ; the upper antennæ are very long and multiarticulate, but the inferior are short and four-jointed. The legs, which are very short, consist of five pairs, each leg being divided into two cylindrical branches. From their curious forms, great agility, and odd motions, these little insects form conspicuous objects in the exhibitions of the solar microscope, with which instrument so much instruction and amusement is capable of being produced. The upper and long antennæ perform the offices of legs, and the lower pair of these organs, from their being kept in a continual rapid motion, produce a kind of whirlpool, which brings into its vortex the minute particles upon which they feed. At the period of coupling the males are extremely active. The eggs which are of a brown, blue or green colour, varying according to their age, become transparent when nearly ready to

produce the young; and it is an extremely curious circumstance, which has been well confirmed, that a single act of impregnation is sufficient for several successive generations. A female cyclops in the space of three months gives birth to not less than ten distinct broods; and if we calculate only eight broods, each having only forty young, it will be seen how immense must be the increase of these creatures. The duration of the egg state varies from two to ten days, according to circumstances, such as the degree of temperature, the period of the year, &c. When hatched, the young have only four legs, with the body of a rounded form, and destitute of tail. Muller, the celebrated Danish writer upon these and other allied animals, not knowing them to be the young of the cyclops, formed them into a distinct genus with the name of *Amyxome*. Shortly afterwards they acquire an additional pair of legs, and these for the same reason were formed by the same author into the genus *Nauplius*. After the first shedding of their skin they are said to possess all the organs of their perfect form, but of a diminished size, especially as regards the antennæ and legs; and that after the third moulting they become adult; but in this manner of reckoning it will follow that two pairs of legs must be developed without a corresponding moulting having taken place, and this is so contrary to what is observed amongst the invertebrated animals that the correctness of such observation may perhaps be questioned. The chief food of these animals consists of minute particles of animal matter floating in the water, but in default of this they will feed upon vegetable substances in a decaying state. When one of the antennæ is cut off no change at first takes place, but at the following moulting the loss is repaired by the production of a new antenna.

There are numerous species belonging to this group, of which the *Monoculus quadricornis* of Linnæus (a name improperly changed by Dr. Leach to *C. vulgaris*) is the type; it is very variable in its colours, being sometimes reddish, at others green, bluish, or whitish. It is a very common species. Some of the species (forming the genus *Calanus* of Dr. Leach, including the *C. finmarchianus* of Muller,) have the inferior antennæ obsolete, whilst others (forming our genus *Canthocampus*, having for its type the *C. staphylinus*), have the abdomen of the females recurved with a spine beneath at the base, and in some there is but a single egg-pouch (forming our genus *Diaptomus*), and of which the *C. castor* is the type.

CYCLOPTERUS, a genus of soft-finned fishes, belonging to the order with the ventral fins under the pectorals, and to the third family of the order *Discoboles*, and including the lump-fish and some others. The following are their most remarkable generic characters:—

The rays of the ventral fins are dispersed all round the lower part of the thorax, and united by a single membrane of considerable strength into a concave oval disc, which the fish employs as a sucker for attaching itself to the rocks. This is their most remarkable character; and it is from it that they get the name of *Cyclopterus*, or fin all round. Their other characters in brief are: the mouth very large, with small pointed teeth in both jaws, and also in the pharynx; their gill lids small, their gill flaps with six rays; their pectorals very large and united below the throat so as to unite with the disc formed by the ventrals; their skeleton is soft and very imperfectly ossi-

fied; and their skin viscous and without scales, but powdered over with small hard grains. Their stomach is large with numerous cæca; their intestine and air bladder of mean size. They are usually divided into two sub-genera, the chief distinction being the form of the dorsal fin.

1. LUMP FISHES: These have a first dorsal fin more or less visible, but always very low and with simple rays; the second dorsal has the rays articulated, and is placed immediately over the anal fin; the body of these fishes is very thick and clumsy, and also very soft, and not very manageable in the water; but they are enabled to hold on upon the rocks by means of the ventral disc, and thus catch the food which is brought to them by the current of the water, and they are much less liable to be injured by the current beating them against the rocks than if their bodies were of firmer texture.

COMMON LUMP FISH (*Cyclopterus lumpus*). This species is common on all the coasts of the British islands, and in most parts of the North Sea. The back is sharp and raised, the belly flat, the body of the fish deep, the dorsal and anal fins short, and the sides marked with rows of osseous tubercles. The length is usually about eighteen inches; the colours—dusky on the back, and red on the under part; the flesh is soft, oily, and tasteless, and seldom used as human food; but as the fish is as lumpish in its motions as in its form, it very readily falls a prey to sharks, seals, and other predatory inhabitants of the waters. It is not understood to eat fish, but rather meduse and other soft and gelatinous animals which float about freely in the water, and are brought to the eddies where it fastens itself upon the rocks. It is sometimes apt to vary in colour, and hence there are different names for it. There are, also, however, one or two smaller species, all inhabiting the North Seas, but of no use or interest whatever.

2. CYCLOGASTER. These have one dorsal fin, of the same length as the animal. Their bodies are smooth, elongated backwards, and considerably compressed, and they are much more active than the former subgenus.

SEA MOUSE (*Cyclopterus musculus*). This is a small fish, about seven or eight inches in length, found on the shores of the Channel; and gets its common name from its colour and the activity of its motions.

THE LIPARIS (*Cyclopterus liparis*). This species grows to a much greater size than the former, being frequently eighteen inches in length. It is a very northerly fish, and found on the icy coasts, though it sometimes makes an excursion as far southward as the shores of England and France. Its muzzle is rounded; its head broad and flat; its mouth large with two small fleshy beards to the upper lip. The back and fins are brown, the sides yellow, and the belly white. The flesh of this species is eaten by some of the northern people, but it is of very inferior quality. There is another species found in the north, chiefly in the White Sea, which is different from this, and has been called *Cyclopterus linetus*, the sides of this species are striped longitudinally with brown and white, and it differs from the former in a few other particulars; but it is a fish of no interest or value.

CYCLOSTOMA (modern authors), (*Helix* of Linnæus, *Turbo* of Muller). The shells constituting this genus are all of them terrestrial, and from the

great variety of their forms have been blended by former writers on conchology with other genera. It now, however, comprehends a well-defined separation from the *Helices*, being easily distinguished by the aperture or mouth being constantly circular, whence the name is derived: the margin is thin, sharp, and outwardly reflexed at right angles with it. The genus *Cyclostoma* is not, however, the only species of mollusc possessing a round mouth; the *Scalaria*, *Delphinula*, and *Paludina*, have it also; the two former have likewise the reflexed lip, but the annular processes or previous terminations of the aperture in the *Scalaria*, and the pearly substance of the other, distinguish and prove them to be marine; while the *Paludina*, not possessing a reflexed lip, but a smooth, sharp margin, is evidently a fluviatile shell. These molluscs vary considerably in form, some being turritured, some quite cylindrical, others flat at the spire, or convex, and can only be recognised with certainty by their round aperture and reflexed lip. Their exterior never having tubercles or spines, and by their possessing a perfect calcareous operculum, not spiral, and the summit sub-central, another distinguishing character may be observed in the left side of the aperture, having its origin much detached from the spire. The genus is subdivided into such species as have the spire slightly elevated, as in the *C. elegans*; those whose spire is very prominent, as in the *C. fasciata*; those umbilicated and trochiform, as the *C. planius*; and, lastly, such as are much depressed, and planorbicular, as the *C. planorbicular*. They inhabit the Indian, African, and American continents; and about twenty-five recent species are described, with eight or ten fossil.

**CYDONIA** (Tournefort) is the common quince of gardens. It is said to be a native of Cydon in Crete, hence the generic name. The quince is too austere in flavour, and disagreeable in scent, to be regarded as a table fruit, but it is useful in combination with others for adding a piquant flavour, and it is also useful for several purposes of the confectioner.

It may be propagated by cuttings, layers, or by suckers, which rise from the root. The tree is of a middling size, and very irregular growth, requiring pruning to keep it in form. It is just possible that this beautiful fruit may be capable of amelioration by cross impregnation with the pear. The only difficulty in the way of accomplishing this result is that the trees do not flower at the same time, so that some management must be had recourse to either to accelerate the flowering of the quince or retard that of the pear. Whether such a thing be practicable we have yet to learn, but the thing deserves consideration.

There are four varieties of the quince, viz. the pear-shaped, the apple-shaped, the Portugal, and the eatable. The Portugal is preferred for marmalade, it yielding a higher colour. They may be grafted on each other, and all thrive in any kind of loamy soil. Quince stocks are often used by nurserymen for some particular sorts of pears, on which they do better than on their own stocks.

**CYMBIDIUM** (Swartz). A genus of fine flowering and sweet-scented herbaceous perennials, natives of China and both Indies. The flowers are gynandrous, and of course the plants belong to the natural order *Orchideæ*. Generic character: sepals distinct, spreading and gaping; three superior ones somewhat hollow and broad, inferior, narrow, and deflexed. Labellum concave, rather lobed, articulated with the base of

the column. Column jointed, winged, and obtuse; anthers terminate and hooded; pollen masses behind in two lobes joined to glands. Some of the species of this genus are remarkable for the brown colour of their flowers, and their night-evolved perfume. The *C. Sinense* is a strong-rooted bulky plant, and requires a large pot to allow vigorous growth in order to flower strongly. This is a great favourite among the Chinese, who grow them well; very fine ones are sometimes valued at 100 dollars! Of such the flower scape or stem rises to the height of four or five feet, with flowers from bottom to the top. This plant is an instance of that remarkable property in all flowers of a brown colour, being most odorous by night. The cymbidiums require to be planted in sandy loam and moor earth, and grown in a pit or frame, and removed into the greenhouse or conservatory when in flower.

**CYMBULIA** (Peron, Lamarck). A cartilaginous shell of crystalline transparency and firm consistency, in the form of an elongated slipper, or French wooden shoe (sabot), truncated at the summit with a lateral opening at the anterior part, conical at the posterior where the animal adheres, having the faculty of concealing itself altogether in its glassy covering. The animal's body is sub-cylindrical, provided backward with a filament, by which it is attached to the shell; on each side is a large natatory appendage; it has two eyes and a kind of proboscis. It is arranged in the second class, *Paracephalophora*, first order *Aporobranchiata*, first family *Thecosomata*.

**CYMOTHOIDEÆ** (Leach). A family of crustaceous animals, belonging to the division *Edriophthalma*, and order *Isopoda*, and distinguished by having the antennæ short, and inserted in pairs one above the other. The body is of an oval form, convex or depressed, the abdominal portion divided into several segments, of which the basal ones are very short, and the terminal one large and broad; the legs are short, and very robust, being terminated by a hooked joint. These animals composed the Fabrician genus *Cymothoa*, but were arranged by Linnæus under the genus *Oniscus*. They have, indeed, somewhat the appearance of wood-lice, but their habits are very distinct, being parasitic upon various kinds of fishes inhabiting the ocean, to which they attach themselves by means of their strong-hooked feet, and then suck their blood; hence the ancients gave them the names of *Estrus* and *Asilus*, from the resemblance between their habits and those of the breeze flies. On the under side of the body of the females are fixed several membranous pectoral imbricated scales, covering the eggs, and in which the young are hatched. Dr. Leach divided this group of animals into numerous genera, but which may be reduced to those of *Serolis* (having the eyes placed upon tubercles), *Nelocera*, and *Cymothoa*, to which *Synodus* and *Linnoria* may be added. The last-named genus comprises a minute animal, which burrows into the wood of which the submarine buildings of several of our dockyards are composed, committing great devastation in such situations. In the genus *Cymothoa* the eyes are not elevated on tubercles, and are formed of minute facets; the abdomen is six-jointed, and the mandibles not porrected. The type of this genus is the *Oniscus asstrum* (Linnæus), a species known to Aristotle, who says of it—"Fishes are attacked by a sea-louse, which is not produced from the fish, but from the mud." It resembles a wood-louse, but the tail is larger.

**CYNANCHIUM** (Linnæus). A genus of herbs and climbing perennials, natives of many different parts of the world. Linnæan class and order *Pentandria Digynia*, and natural order *Asclepiadaceæ*. Generic character: corolla five-cleft and rotate; corona like petals, alternating with anthers, or simply five-lobed; or double, in which case the exterior is ten and interior five cleft. Some few of the species were formerly called *Asclepias*, and are hardy; some are stove, others greenhouse plants. They may all be increased by cuttings or divisions of the roots.

**CYNARA** (Linnæus) is the generic name of the **ARTICHOKE**, which see.

**CYNIPIDÆ**, Nob.; (*Diplolepariæ*, Latreille). A family of hymenopterous insects, belonging to the section *Securifera* (or those which are not furnished with a poisonous sting), and placed by Latreille in the midst of his group of parasitic species, which he has termed *Pupivora*, notwithstanding the circumstances that the species of which the family is composed are herbivorous in their larva state. These insects are small four-winged flies, formed by Linnæus into the genus *Cynips*. The wings are furnished with but few nerves, the lower pair having but a single longitudinal nervure; the antennæ are moderately long and slender, or slightly thickened at the tips, and composed of from thirteen to fifteen joints, not being elbowed in the middle. The abdomen is short, compressed, and of a rounded form, and the ovipositor, which is rather long, is rolled in a spiral manner within the curve of this part of the body, its extremity being only exposed, and which, when not in action, is lodged in a groove at the extremity, formed of two flattened plates.

Much confusion has occurred in the name of this group of insects owing to the incorrect nomenclature introduced by Geoffroy, and adopted by Latreille, the Linnæan name *Cynips* having been applied to the insects composing our family *Chalcididæ* (which see), and the new name of *Diplolepis* given to the Linnæan *Cynipes*. In a paper upon this subject, published in the Zoological Journal, the author of this article corrected this synonyme, and has the gratification to have been followed by Latreille in his last work, where the family *Chalcididæ* is described under the name of *Chalcidites*, although the gall-flies, instead of being similarly named *Cynipites*, are termed *Gallicolæ*, in allusion to the habits of the family, of which the species, or at least their retreats, are well known to every observer of nature under the form of galls and excrescences of different shapes upon various kinds of trees. The insects are of small size, and, as it were, hunch-backed, owing to the small size and low position of the head, and the elevated thorax. The galls which we have mentioned are the result of wounds inflicted by the parent *Cynips* upon the leaves, or bark of various plants, in the act of depositing her eggs, and which are thrust into the wound thus made. How their growth, however, is effected, is a point in the natural history of these insects not yet determined, and it is only by the microscopic observation of some of our vegetable physiologists that we can hope to obtain a satisfactory solution of the question. It is indeed difficult to conceive how a minute egg, deposited in the middle of a leaf, shall, in a short time, be found removed from such situation, and fixed in the centre of a vegetable mass, sometimes as much as an inch from its original position, such mass being in some cases dependent from the leaf at the extre-

mity of a slender thread, somewhat like a cherry at the end of its stalk. It is equally curious to consider the great virulence of the fluid deposited by the parent with the egg, and which has evidently the effect of irritating the plant to such a degree as to cause it to throw out these monstrous appendages. It was indeed supposed by the early naturalists that these galls were caused by the larvæ when newly hatched, gnawing the leaf, thereby causing its juices to flow, by which it was soon surrounded, and which soon became inspissated; but as the galls are often found fully formed even before the egg is hatched, this opinion is untenable. But, even to the philosophical Redi, these insects proved a stumbling block; for, notwithstanding all his splendid discoveries and observations, whereby he so satisfactorily disproved the doctrine of spontaneous generation, he fell into the strange idea, in order to account for the development of these galls, that there existed in the trees and plants a vegetative kind of power, or soul, charged with the care of producing the grubs; and if, says Reaumur, we are not disposed to admit that a merely vegetative power would produce a gall and a gall-worm, he was even disposed to believe it to be still more sensitive. How humiliating is it to the proud intellectual powers of the mind, that so absurd an idea could have entered into the mind of Redi. Our great philosopher, John Ray, after noticing this fancy of Redi, and the received opinion that some insects were produced from plants, tells us that "Signior Malpighi, in his Treatise of Galls, under which name he comprehends all preternatural and morbose tumours and excrescences of plants, doth demonstrate, in particular, that all such warts, tumours, and excrescences where any insects are found, are excited or raised up either by some venenose liquid, which, together with their eggs, such insects shed upon the leaves, or buds, or fruits of plants, or, boring with their terebræ, instil into the very pulp of such buds or fruits, or, by the contagious vapour of the very eggs themselves, producing a mortification or syderation in the parts of plants on which they are laid; or lastly, by the grubs or maggots hatched of the eggs laid there, making their way with their teeth into the buds, leaves, or fruit, or even the wood itself of such plants on which the eggs were laid. We conclude, therefore, that galls and other tumours of plants are nothing else but morbose excrescences raised up by the force of the egg there laid, disturbing the vegetation and temper of the plants, and perverting the motion of their humours and juices, wherein the inclosed eggs and animalcules are cherished, nourished, and augmented, till their proper parts being manifested, explicated, and hardened and strengthened, they are, as it were, new born, affecting to come forth into the open air."—*Wisdom of God*, p. 249.

Some authors have considered that these galls are leaves or buds modified into galls by the action of the stimulating matter left in the wounds, whilst a more recent writer has supposed the orifice of the wound or the egg itself to be covered with gluten\*, which gluten prevents the sap that flows through the puncture from being scattered over the leaf, and the sap being thus confined to the space occupied by the eggs, will expand and force outwards the pellicle of gluten that confines it, (and which, of course, forms a

\* We do not well understand how the sap can flow through a puncture stopped with gluten.

covering or coating to the entire gall,) till becoming thickened by evaporation and exposure to the air, it at length shuts up the puncture, stops the further escape of the sap, and the process is completed. When, however, we consider the large size of some of these galls and the very minute quantity of gluten which must be deposited with it, we do not see sufficient cause for adopting this idea; moreover we cannot but suppose that a more irritating fluid than mere gluten is deposited, in order to produce such active and violent effects upon the plant. If, indeed, the *Cynips* did not belong to the *Hymenoptera*, we might feel less hesitation in thus expressing ourselves; but when we know, from experience, the poisonous fluid with which even the terebrant *Hymenoptera* are furnished, it is difficult not to believe that it is to this stimulus that the production of these galls are attributable; but, again, admitting the orifice to be stopped by gluten, we see but little difficulty in supposing that the vegetative matter, of which the gall is formed, should not require a coating of gluten any more than though it were a leaf or a bud. But when this theory is applied in detail, we find it still more untenable; indeed, its author was obliged to admit that, in the hairy bedeguar gall of the rose, "the gluten, it would appear, is not sufficiently tenacious to confine the flowing sap within the dimensions of any of the little clustered globes containing the eggs, for it oozes out from numerous cracks or pores in the pellicle," and "shoots into a reddish-coloured fibrous bristle,"—and from the natural tendency of the sap of the rose-tree to form prickles, these are all studded over with weak pricklets; which formation is supposed to be of great utility by affording warmth during the winter to the enclosed insects. Without stopping to inquire why the gluten of the bedeguar should not be as strong as that of the much larger oak gall, we will only observe, in conclusion, that the circumstance that many of the different kinds of galls are so irregular in their forms, bearing resemblance to leaves and buds, that it is impossible to apply to them, or indeed to any other than perfectly globular galls, the theory of the gluten; and it is not philosophical to suppose that the globular galls should be produced by one operation; and the other kinds by a distinct one.

One of the best known species of galls is that employed in the manufacture of ink, and which is found upon the oaks growing in the Levant. This gall is of a globular form, and on opening it, its interior will be found to be of a very solid consistence, having a rounded cell in the centre, in which the fly (*Cynips galle tinctoriæ*) in its winged state may often be found. The form and solidity of galls vary according to the situations in which they are found, as the leaves, peduncles, buds, bark, root, &c.: some being round, others irregular, some smooth, others covered with hair, whilst many resemble buds or minute artichokes; their size is also very varied\*.

It is a curious circumstance that the eggs of these gall-flies, like those of the saw-flies, increase considerably in size previous to the exclusion of the larva, which is sufficient to show that the membranous covering in which they are enclosed is of a very different texture from that which envelops the eggs of insects in general. The larva hatched from these

eggs are white, fleshy, inactive grubs, destitute of legs, which would, of course, be useless to them, but provided with jaws for eating the hard substance of the gall. Sometimes one only inhabits a single gall; but in others a single gall is the abode of numerous larvæ. In some species the larvæ undergo their transformations, and the perfect insect is produced within the gall; but in others the larvæ make their way out of the gall when full-grown, and fall to the earth, where they become pupæ. The exit of the insect in either state from the gall is indicated by a small circular orifice at the side of the gall. These gall insects are much subject to the attacks of a parasitic group of flies, of nearly the same size, belonging to the family *Chalcididæ*, and having the ovipositor long and exserted, their colours being highly metallic and beautiful; they compose the genus *Cullinome*.

One of the species of this genus is employed in Greece in a very serviceable manner for hastening the maturity of the fig. This species, which is the *Cynips pænes*, deposits its eggs in the seed vessel of this plant, and the inhabitants place a quantity of the early figs which had been attacked in the neighbourhood of the more tardy ones; so that the insects when quitting the former, covered with the secondary dust, introduce themselves into the latter, so as to cause the more speedy ripening of the fruit. This process is termed caprifigation.

Hitherto all the species of this family have been considered as inhabiting galls, but in a memoir which the author of this article has lately published in the Magazine of Natural History, we have given the history of a species which we discovered to be parasitic upon the aphides of the rose, in which respects it forms an interesting point of connection between such of the *Ichneumonidæ*, as the *Aphidius*, (see *BRACONIDÆ*), and the true gall-flies.

Oak-apple gall and *Cynips quercusfolii*.

The family comprises the genera *Cynips*, *Figites*, *Italia*, *Anacharis*, and a few others, which we have proposed in the memoir above referred to; these genera rest chiefly upon structural differences. The typical genus, *Cynips*, has the abdomen compressed and the antennæ filiform; the submarginal cells are three in number. The oak-apples are produced from one of the species of this genus, *Cynips quercusfolii*, and the bedeguar, (which see,) is the result of the wounds of the *Cynips roseæ*, a species of moderate size, of black colour, having the legs and abdomen, except at the tip, red.

**CYNOGLOSSUM** (Linnæus). A genus of herbaceous herbs, mostly biennials, and natives of Europe. Two of the species are British, and called, from the shape of the leaves *Hound's-tongue*. It belongs to the fifth class and first order of Linnæus, and to the natural order *Boraginææ*. The cynoglossums are used as open border flowering plants, but do not possess much beauty. They are increased by seeds.

\* We must refer to our article *CUPULIFERÆ* for various details relating to the economical usages to which galls are applied.

**CYNOSURUS** (Linnæus) is the dog's-tail grass of British farmers, and a useful grass both in meadows and pastures, and when prevalent enhances the value of hay.

**CYNTHIA**, (Fabricius). A handsome genus of lepidopterous insects, belonging to the section *Diurna*, and family *Nymphalidæ*, having the wings scalloped, the anterior triangular, and somewhat hooked; the antennæ have an abrupt, short, terminal club; the larva is spinose, and the chrysalis ornamented with golden spots, and of an angulated form. The only British species is the *Papilio cardui* of Linnæus, termed the painted lady; it is of a rosy buff colour, with black and white markings, the lower wings being marbled beneath, with four eyelets; the larva feeds solitarily upon various kinds of thistles, nettles, &c. beneath a silken web; the chrysalis is of a greyish colour. It appears in the spring, and again in August, but its appearance is very irregular, several seasons intervening before it is again met with. This is one of those species which with certain trifling alterations are met with in almost every quarter of the globe.

**CYPELLA** (Herbert). A bulbous-stemmed herbaceous perennial, introduced into this country from Buenos Ayres. It belongs to *Iridææ*. This bulb requires to be planted in a warm border, where it flowers and ripens seed in summer, but should be protected from frost in winter.

**CYPERACEÆ**—the sedge family. A natural order of monocotyledonous or endogenous plants containing nearly thirty genera, and between four and five hundred known species. It bears a strong affinity to *Gramineæ* or grasses, and by superficial observers would at once be referred to this family. It differs, however, in its solid and angular stem, in the absence of a diaphragm at the articulations, in the flowers being covered by a single bractea, and in the embryo lying at one end of the albumen, within which its cotyledonary extremity is included. In its general habit this order is also allied to *Junceæ* and *Restiaceæ*. Its essential characters are: flowers hermaphrodite or unisexual, each with a glume or chaffy scale; perianth either wanting or resembling bristles, rarely membranaceous; stamens hypogynous, definite, generally three; anthers fixed by their base, entire, two-celled; ovary one-seeded, often surrounded by bristles; ovule erect; style single, trifid, or bifid; stigmas undivided, occasionally bifid; fruit a crustaceous or hard nut; albumen of the same figure as the seed; embryo lenticular, undivided, enclosed within the base of the albumen; plumule inconspicuous.

The plants belonging to the order are herbs with fibrous roots, angular stems generally without joints, sheathing leaves, the sheath being entire, and spirate glumes, the lowermost of which are sometimes empty and sterile. They are extensively distributed all over the globe, and are found growing in marshes, ditches, and streams, in woods and meadows, on the sands of the sea-shore, and on the tops of mountains. In the northern regions, cyperaceæ are numerous, and bear nearly an equal proportion to the true grasses, but as we approach the equator the number of the species diminishes much, and at the same time the character of the genera becomes changed.

By some authors the order has been divided into four sections:—I. The true *Cyperaceæ*: II. *Scripeæ*; III. *Sclerineæ*; IV. *Caricineæ*. The chief genera are,

*Cyperus*, *Scirpus*, *Sclerina*, *Carex*, *Uncinia*, *Schœnus*, *Rhynchospora*, *Eleocharis*, *Cladium*, *Mariscus*, *Eriophorum*, and *Kyllinga*.

The plants of this order possess in general mucilaginous and demulcent properties, but they are not much used in medicine. They are not celebrated for their nutritive qualities, and are scarcely eaten by cattle. In these respects a wide difference exists between them and the grasses. They are by no means ornamental, and are not used in agriculture. In some sandy districts they are useful in binding the soil.

Of the genus *Cyperus*, whence the name of the order is derived, there are 237 species already described, and of these only two are natives of Britain. Most of the species are tropical, and their number gradually diminishes as we recede from the tropics. Some of them yield tubers which are esculent.

The root of *Cyperus longus*, sweet cyperus or English galingale, has an agreeable aromatic odour and an astringent bitter taste, and has been used as a tonic and stomachic. *Cyperus rotundus*, a native of the south of Europe and Asia, produces bitter tuberos roots about the size of a nut, which are said to be employed successfully by the Hindoos in cases of cholera. On account of their fragrance they are used in Greece to keep away insects from clothes. The tubers of *C. perennis*, after being dried and powdered, are used by the Indian ladies for scouring and perfuming their hair. The root of *C. odoratus* has a fragrant odour and a warm aromatic taste. *C. hydra* is a troublesome weed in sugar plantations in the West Indies. The tubers of *C. esculentus* have an agreeable sweet taste, and are eaten in Spain, Italy, and Egypt. They consist of starch, fixed oil, sugar, albumen, gum, malic acid, vegeto-animal matter, and a substance analogous to tannin, various salts of potash and lime, and some oxide of iron. The starchy matter constitutes the chief portion of the root. The fixed oil which has an amber colour, and a slightly aromatic taste, forms a sixth part of it. In Germany the tubers when roasted are used as a substitute for coffee. *C. papyrus* is interesting on account of being the plant which yielded the papyrus of the Egyptians, whence the English word paper is derived. This plant is now rare in Egypt, and is not cultivated as in former times, when it constituted a source of riches to the inhabitants of the borders of the ancient lakes of Meuzaleh and Bourlos. It is still found growing in marshy places in some of the countries bordering on the Mediterranean. The papyrus or paper of the ancients was made from the cellular substance or inner rind of the stem, thin slices of which were laid over each other transversely, moistened and subjected to considerable pressure. They were afterwards exposed to the rays of the sun, so as to acquire a sufficient degree of dryness, and were ultimately sized. The slices cohered together by means of the mucilaginous matter which enters into their composition. This paper was formerly made on a large scale at Alexandria and other Egyptian cities, and yielded a considerable revenue both to the manufacturers and the government. The mode in which it was prepared was for a long time lost, and has been only recently discovered by some Egyptian travellers.

This plant was used by the Egyptians as medicine, food, and fuel. Sugar was procured from it, and its fibres were manufactured into canvas and ropes. The top of the stalk, with the umbel of flowers,

adorned the temples and crowned the statues of the gods. Boats were made from the plant, and its root was frequently chewed.

*Scirpus* is another genus of the order, some of the species of which are applied to economical uses. *Scirpus lacustris*, lake club-rush or bull-rush, is frequent on the margins of lakes and ponds in Britain. Its stems constitute a considerable article of trade in consequence of being used for mats, chair-bottoms, &c. They are employed by coopers to fill up the spaces between the seams of casks. *Scirpus maritimus*, another British species, is eaten by cattle. Its roots have been ground and used instead of flour in times of scarcity. *Scirpus tuberosus*, the water-chestnut of the Chinese, yields tubers which are eaten either boiled or raw. Many other species of the genus are used for domestic purposes, such as stuffing cushions, and forming the wicks of candles.

*Eleocharis caespitosa*, scaly-stalked spike-rush, is abundant in moist heaths in this country. It is called *Deer's-hair* in the Highlands, and in spring yields an abundant food to sheep on the mountains.

The genus *Carex* furnishes numerous species which grow in swamps, bogs, fens, and marshes, and which are often with great difficulty distinguished by botanists. The known British species amount to sixty-three. With the exception of a few species, they are of little use or beauty. In Kent the larger species are used for tying hops to the poles. In Italy they are put between the staves of wine casks, and are used for the purpose of covering Florence flasks. The roots of *Carex arenaria*, *disticha*, *hirta*, are slightly aromatic, and possess diaphoretic and demulcent properties. They are used as a substitute for sarsaparilla, and are commonly known by the name of German sarsaparilla. The first of these species is common on the shores of Britain, and is useful in binding together the loose sand. *Carex sylvatica*, when carded and dressed, is used by the Laplanders to protect their feet from cold. *Carex Fraseri* is the handsomest species of the genus, resembling at a short distance, when in flower, some of the lily tribe.

The various species of *Eriophorum* receive the name of cotton grass, on account of the silky tufts of a wool-like substance which cover their seeds, and which render some of them peculiarly conspicuous in almost all marshy grounds in this country.

CYPHONIDÆ. A sub-family of coleopterous insects. See CABRIONIDÆ.

CYPRESS. See CUPRESSUS.

CYPRICARDIA (Lamarck), CHAMA (Gmelin). This genus of shells has been separated from the *Chama*, by Lamarck; it nearly approximates to the genus *Cardita* in form, but may be easily distinguished from it by having three teeth beneath the apices, like those of the *C. Venus*, in addition to the callous lengthened tooth or ridge; the ligament is very long, but slightly or not at all projecting, the abdominal impression sometimes placed anteriorly. The animal, according to Poli, is nearly similar to that of the *Cardita*, in consequence of which modern authors have made, this genus a sub-division of the genus *Cardita*. The species appear to inhabit rocks, only occasionally covered by the influx of the tides, in the warm latitudes. The genus is placed in the third class, *Acephalophora*, second order *Rudista*, sixth family *Submytilacea*.

CYPRINA (Lamarck), VENUS (Linnaeus). This genus of molluscs appears intermediate with the

genera *Cyclas* and *Venus*. The *Cyprina* are, in general, of a large size, much resembling the *Veneres*, but are distinguished from them by having one impressed lateral tooth on the front side, sometimes obsolete, the callosities of the hinge are large, arched, terminated near the apices by a cavity, sometimes very deep; the ligament is external, partly fixed beneath the apices. From the molluscs of this genus possessing a lateral tooth, though it is sometimes obsolete, and their being covered with an epidermis, they may be conjectured to inhabit rivers at their junction with the sea. The form of the shell is regular, longitudinally substriated, equivalve, inequilateral, the summits very much recurved forward and often contiguous; the muscular impressions sub-circular, very distant, united by a straight ligula, marginal, and a little sinuous towards the anterior; the impression of the retractor muscle, anterior to the foot, very large and united to that of the adductor muscle; the shell possesses an epidermis, and in substance it is thick and heavy. The animal has been described by Fabricius, but it requires a further knowledge of its organisation to enable us to adopt his definition, which is very obscure; it is, however, by analogous reasoning placed in the third class *Acephalophora*, second order *Rudista*, eighth family *Conchacea*. Not more than two or three recent species are known, and about seven fossil. It inhabits northern climates, and one species is a native of Iceland.

CYPRINOIDÆ—The Carp family. The first of the five families into which Cuvier divides his first order of soft-finned fishes, or those which have abdominal fins, that is, which have the ventral fins attached to the abdomen behind the pectorals, and unconnected with the bone of the shoulder.

This family have the mouth small, the jaws feeble, with little opening, and very often without teeth, but with teeth on the pharynx, which compensate a little for their absence from the jaws. Their bodies are scaly, and they have not the soft dorsal fin which is found in the salmon family. They are the least carnivorous of all the finny tribes. They are all inhabitants of the fresh water, and there is such resemblance among them, that it is often difficult to distinguish the one from the other. Most of them are esculent, but their flesh is not of the first quality. Cuvier divides them into eight genera: *Cyprinus*, the carp; *Cobitis*, loche; *Anableps*; *Pacilia*; *Labias*; *Fundulus*; *Molinesia*; and *Cyprinodon*; some short account of each of which will be given in its place in the alphabetical order of this work.

The genus *Cyprinus* is farther divided into eleven sub-genera: *Carp*, properly so called, which is the typical sub-genus; *Barbus*, the barbel, of which an account will be found in the article BARBEL; *Gobio*, the gudgeon; *Tinca*, the tench; *Cirrhinus*; *Abrama*, the bream; *Labes*; *Catostomus*; *Leuciscus*; and *Gonorhynchus*. Some account of such of these as have any interest for the general reader, will also be found, either under their generic names, or their English ones, where they have any; and, therefore, the remainder of this short notice may be restricted to a very brief mention of carp, properly so called.

CARP (*Cyprinus*). These have the dorsal fin longer than the other, with a toothed spine for the second ray of the dorsal and caudal fin. Some have fleshy beards, or filaments at the angles of the upper jaw, and others are without.

COMMON CARP (*Cyprinus carpio*). This species

has four beards to the mouth, the lateral line a little bent, and the tail forked. It is not understood to be a native of England, but to have been introduced as a pond-fish about the latter part of the fifteenth century. It is found native in the lakes and ponds of the south of Europe, and it is much more common in France and in Germany than in this country. Its flesh is tolerably good, and it is serviceable as a pond-fish, because it is remarkably tenacious of life, and therefore can be carried over land from one place to another. Instances are mentioned of its having been carried alive from Strasburg to Paris, by keeping a little humid moss in contact with the gill-lids; and, indeed, it will live a long time without even that simple operation.

Carp is not a fish of the troubled waters, and its motions are as restrained as those of the element in which it lives. Placid streams, which creep along without any perceptible current, the moats and trenches of ruined castles, shaded and mantling ponds, which are left to the operations of nature, and in which aquatic plants accumulate, are the favourite localities of carp. It feeds quietly upon those submerged vegetables; and from the quietness of its habits, and the little fatigue which it undergoes, it lives to a great age, not less, it is said, than a hundred years, by which time its back is understood to get entirely white. It is not timid, but rather fond of society, and capable of being so far educated, as to come and be fed at stated hours, on being whistled to by its master. The stilly part of the Rhine, near Strasburg, contains immense numbers of carp, in which a considerable trade is carried on with Paris; and it is found as far to the eastward as Persia; but it is understood to prefer more temperate climates, and does not grow to so large a size in very warm countries. Specimens have been mentioned of nearly four feet in length, but it is rare to meet with one more than two. Though the carp feeds a good deal upon vegetable matter, it also eats worms and aquatic insects, and, as is sometimes said, it swallows the mud at the bottom of its haunts for the sake of the larvæ, and seeds which are contained in that. Hence the flavour of its flesh varies, much depending on the nature of its food. Carps spawn in June, and are very prolific.

Besides the common carp, there are mentioned, the *King of the Carps* (*Rex cyprinorum*), but it is doubtful whether this is a species; yet its scales are remarkably large, often an inch in length, and it appears to be more northerly than the other; also, the *Ann-Carolina* Carp, of Lacépède, a Chinese species, very handsome and beautifully coloured; and the *Green-violet*, of the same author; but little is known respecting them.

Of those which are without beards to the jaw, the most celebrated is—

The **GOLDEN CARP** (*Cyprinus auratus*). This is the well-known gold fish from China, and needs no description. A silver fish from Asia is also mentioned, but it is possible that this may be nothing more than the former discoloured by age.

CYPRIPEDIUM (Linnæus), is one of the most interesting of the *Orchideæ*. The *C. calceolus* is a native of Britain, and one of the most curious of her productions. Generic character: sepals patulate and distinct, the upper ones often united like a helmet, the two lateral ones divaricating; labellum inflated; upper part of the column trifid, lateral lobes bearing

anthers, middle one sterile and glandular; pollen granular. This, as well as the American species, should be planted in moor earth, in a frame or shady border, and defended from severe frost and heavy rain. They sometimes ripen seeds, by which they may be increased.

CYPRIS (Muller). A genus of minute crustaceous animals belonging to the sub-class *Entomostraca* and order *Branchiopoda* (which see). These little creatures swim about with great velocity in standing and fresh waters, their bodies being inclosed in a kind of bivalve case united by a hinge, which enables them to close their shells on the approach of danger. They have only six legs, and the antennæ are terminated by a whorl of hairs like a pencil; the body is without distinct articulation, terminated posteriorly by a soft tail. According to Jurine, who has observed these insects with much attention, the antennæ are employed in swimming, and the two fore legs are used when the animal creeps upon the surface of aquatic plants. He says that the second pair of legs are employed in establishing a motion in the fluid, whereby small particles of food are directed to the mouth; the tail is divided by two fillets, which are folded together when coming out of the shell; the eggs are enclosed in two large bags at the sides of the body beneath the shell; the female is occupied for about twelve hours in depositing them upon aquatic plants. As in the *Cyclops*, Jurine observed that several generations are capable of being produced without more than a single coupling having previously taken place. There are numerous species, inhabitants of our standing waters. The allied genus, *Cythera* of Muller, has eight legs, and the antennæ are not terminated by a brush; the species of this genus are confined to the salt water of the ocean.

CYRENA (Lamarek). A genus of shells, united to the genus *Cyclos* by de Blainville, of which he makes it a subdivision with considerable propriety. These shells are found in rapid rivers and streams; they are thick and solid shells, sometimes of great size; the apices eroded or carious, covered with a green or brownish epidermis, and admirably constructed to endure, the rough treatment they experience from their peculiar habitations; their classification will be seen under the article *Cyclos*.

CYRTANDRACEÆ, a natural order of dicotyledonous plants, containing only a few genera and species. By Don and some other botanists it is denominated *Didymocarpeæ*. It is closely allied to *Gesneriæ*, from which, however, it differs in its deeply-lobed placentas, its siliquose fruit, and the want of albumen. It also bears a strong affinity to *Bignoniaceæ* and *Pedalineeæ*, from which it is distinguished by its herbaceous growth, its minute, indefinite, wingless seeds, its one-celled ovary, and the membranous texture of its fruit and placentæ. Its essential characters are: calyx bell-shaped, five-cleft or five-leaved, equal; corolla tubular, irregular, five-lobed, somewhat two-lipped, the lobes imbricated in aestivation; stamens four, didynamous, of which two are sometimes sterile; anthers two-celled; ovary superior, elongated, surrounded by an annular disc, one-celled, with two many-seeded placentas, each of which consists of two diverging plates; style filiform; stigma two-lobed, and consisting of two plates; fruit capsular or succulent, the former siliquose and two-valved, one-celled, with double longitudinal placentas, which often cohere, so as to give the appearance of two cells; seeds very

numerous, minute, suspended, naked or connate; albumen none; embryo straight cylindrical; radicle next the hilum.

The plants belonging to the order are either terrestrial or parasitic, and usually herbaceous and stemless. They are sometimes shrubby; their leaves are generally opposite and radical, while their flowers are umbellate and often of a purple or pink colour.

They are found chiefly in the tropical regions of the Old World. Their properties have not as yet been determined.

The chief genera are *Cyrtandra*, *Didymocarpus*, *Chirita*, and *Incarvillea*.

**CYRTANTHUS** (Hortus Kewensis). A genus of Cape bulbs, belonging to *Hexandria Monogynia*, and to the natural order *Amaryllidææ*. Generic character: spatha few, or many-flowered on an umbel; corolla tubular, curved, enlarged above, limb erect and six-cleft; stamens inserted in the tube; filaments like threads; anthers incumbent; style protruding; stigma trifid; seed-vessel three-celled. This genus, like many other bulbous plants from the same country, do well when grown in a pit or frame. While dormant, very little water should be given, but a large share when in full growth. Turfy loam and sand, or moor earth, is a suitable soil, and it is well to shift them just before they commence the summer growth. They are increased by seeds or offsets.

**CYTHERIA** (Lamarck), **VENUS** (Gmelin). This genus, notwithstanding the number of its species, was blended by Linnæus with the genus *Venus*, contributing to render that an overgrown and badly defined family. Lamarck observes that a great difficulty exists in discovering the characters of some of the species, the shades of difference between them being so slightly defined; he has, however, pointed out as a general guide to distinguish them from the genus *Venus*, that they have all of them four primary teeth on one valve, and only three united on the other, with an isolated cavity, oval, and parallel to the margin, the lateral teeth divergent to the summit. "They are all marine shells, solid, regular, equivalve, inequilateral, apices equal, recurved, and slightly projecting. We are not positively determined upon the propriety of adopting this genus in its present form, but give Lamarck's definition until other reasons can be adduced for changing his arrangement. Our object being rather to illustrate the genera of modern authors than to introduce new ones of our own creation, which would lead to endless controversy, we nevertheless shall always freely express our opinion where it is founded upon our own experience, or the well authenticated observation of intelligent naturalists.

**CYTINEÆ**. A natural order of dicotyledonous plants, containing only a few genera and species. This order exhibits, in some degree, the structure of both the vascular or flowering, and the cellular, or flowerless class of vegetables—agreeing with the former in having a distinct floral envelope, and obvious sexual organs, and with the latter in the absence of spiral vessels, and the peculiar structure of its seeds, in which no appearance of radicle or cotyledons can be detected. Among the phænogamic tribe of plants, this order bears the closest affinity to *Aristolochiææ*. Its essential characters are: flowers diœcious, monœcious, or hermaphrodite; perianth adherent with the ovary, the limb in several divisions, which are imbricated in æstivation; stamens adhering in a solid central column, from the apex of which

sometimes arise horned processes; anthers adnate, either bursting longitudinally and externally, or having their inside cellular, and discharging their pollen by orifices at the apex; ovary adnate, with the tube of the perianth one or many-celled, with broad parietal placentas, which are covered with an indefinite number of minute ovules; fruit an inferior pulpy berry; seeds extremely minute.

The species belonging to this order are curious parasitical brown or colourless plants, having simple stems, which are covered with a few scales in place of leaves, and bearing flowers which grow in spikes or heads, and are sometimes solitary. They are found in the south of Europe, and also in the eastern Archipelago.

In general, the properties of the order may be said to be astringent.

The chief genera are *Cytinus* and *Rafflesia*.

*Cytinus hypocistis*, rape of cistus, is a fleshy pale yellowish plant, found parasitic on the roots of several species of *Cistus* in the south of Europe. The astringency of the plant is owing to the presence of gallic acid. An infusion of it is said to precipitate gelatin.

*Rafflesia Arnoldi*, or *Titan*, a native of Sumatra and Java, where it was first discovered in 1818, is perhaps the most extraordinary vegetable production in the world. It has neither stem nor leaves, and consists only of an enormous flower, three feet and a half in diameter, and fifteen pounds in weight, which grows as a parasite on the stem of a kind of vine. The flower consists of five petals, of a brick-red colour, and from a quarter to three quarters of an inch in thickness. In Java it is used as a powerful astringent.

A minute botanical description, and an accurate figure of the plant, are given in the thirteenth volume of the Transactions of the Linnæan Society.

**CZACKIA** (Andrews). An herbaceous perennial, a native of the south of Europe. It belongs to *Hexandria Monogynia*, and to the order *Asphodeleææ*. This plant was formerly known by the names of *Anthericum liliastrium*, and *Hemerocallis liliastrium*; but is now as above, *C. liliastrium*. It is a good border flower, likes a rich soil, and is propagated by dividing at the root, or by seeds.

**DACRYDIUM** (Solander). A New Zealand genus, belonging to the class and order *Monœcia Monadelphia*, and to the natural order *Coniferaææ*. This tree is nearly allied to the genus *Cypress*, and has been, since its introduction into our greenhouses, called the New Zealand Spruce. It grows well in loam and moor earth, and may be propagated by cuttings planted in a pot of sand covered with a hand-glass. It was called *Thalamia cypressina* by Sprengel.

**DACTYLIS** (Linnæus), is the generic name of the common British grass, called Cocksfoot (which see).

**DAFFODIL**, is the ordinary name of a very common British plant, and which is one of the earliest ornaments of our cottage gardens, as well as of many of our woods and meadows. It is one of the most conspicuous species of the *Narcissus* family, and of course ranks among the *Amaryllidæææ*. Many varieties of the daffodil are in cultivation, differing from each other chiefly in bulk, and in the structure of the flower. But no change has yet taken place in the original colour of the flower, it still retaining its deep yellow hue.

**DAHLIA** (Cavanilles). A large south American tuberous-rooted herbaceous plant, introduced *via* Spain in 1789. It belongs to the class and order *Syngenesia superflua* of the sexual system, and to the natural order *Compositæ*. This plant is now so common as to need no specific description. It is met with everywhere, in the garden of every cottage as well as of every palace, and among cultivators, in such quantities that it is truly astonishing to conceive where a vent can be had for them. No plant has been more extensively cultivated than the dahlia, and no plant has repaid the labour and care bestowed on it with more varied forms and colours than this. In form and stature it is a Proteus; in tints it is a vegetable prism. Neither is the form nor colours constant in the same individual. The first flowers will be single, and of one colour, and the last double, and of another hue; and such is the versatility of the self-colour of a parent, that its seedlings will be edged, or striped, or blotched, and altogether as unlike the mother as change of colour can make them.

The dahlia partakes very much of the nature of the potato; they are natives of the same quarter of the world, flourish with us during our summer, and, being both tuberous-rooted plants, liable to suffer from frost, require to be taken from the ground and winter-stored in the same secure manner.

There are many different plans resorted to in growing the dahlia. Every cultivator aims at having plants of diminutive stature, bearing numerous, large, and richly-coloured flowers. For this purpose, the following rules are laid down by the most successful growers: About the 20th of February, the tubers are taken out of the dry sand, or from off the shelves in and on which they have been stored for the winter, and partly buried in the bark-bed of a hothouse, or the dry soil of a mild hotbed made up for the purpose. Here they very quickly produce shoots. When these are about four inches long, slip them off, and pot them singly in proper compost, replunge them in the bed, where they may remain till the season allows of them being turned out into the borders.

The young plants can seldom be placed out of doors with safety till after the middle of May; and if, at planting time, they be tall or slender, they should be staked, to prevent injury from wind; and as they gain height and volume in the course of the summer very strong staking will be necessary.

They should not have too rich soil to grow in; dung should never be used, because this only encourages luxuriance of stems and foliage, without either expediting flowering, or causing an increase of size or beauty of the blossoms. The following compost is much used and approved of:—One-fourth mellow loam, one-fourth leaf mould, one-fourth fresh turf soil, and a like quantity of pit or river sand of pure quality and white colour.

A very extensive and successful cultivator was asked the other day whether or not the *dahlia-fancy* was nearly over? He replied, it was only beginning! for, notwithstanding the vast number of magnificent varieties now in cultivation, they would soon give way to other various tinted kinds which are every year raised from seeds. All are endeavouring to raise a *blue* variety—an object, according to Professor Decandolle, which is never likely to be seen.

**DAHOON**, is the specific name of a species of holly found in Carolina, and introduced into our gardens as far back as 1726.

**DAISY**, is the *Bellis perennis* of Linnaeus, and one of our most common British pasture plants. Its humble growth, and pretty little composite flowers, are one of the principal spring ornaments of every piece of turf: There are three garden varieties of it, viz. the large double, the double quilled, and the profuse, or hen-and-chicken daisy, all common in flower borders, and sometimes planted as edgings to them.

**DALBERGIA** (Roxburgh). A genus of stately trees and twining shrubs, natives of the East Indies. Linnaean class and order, *Diadelphia Decandria*, and natural order *Leguminosæ*. Generic character: calyx bell-shaped, five-toothed; keel split at the base; pod on a membranous footstalk, not opening, and containing from one to three seeds. These plants grow well in sandy loam, and are propagated by cuttings struck in sand.

**DALEA** (Linnaeus). A genus of annual and perennial herbs, natives of central America. They belong to *Monadelphia Decandria*, and to the natural order *Leguminosæ*. This genus is allied to *Psoralea* and *Galega*. Several species of it are kept in our greenhouses, and propagated by cuttings, but which, if exposed to much humidity, are liable to drop off.

**DALECHAMPIA** (Linnaeus). A climbing tropical genus of plants, natives of Brazil, belonging to *Diacia Diandria*, and natural order *Euphorbiaceæ*. These are seen in stove collections, and are grown in loam and moor-earth, and are easily propagated by cuttings.

**DAMMARA** (Rumphius). A genus of lofty-growing forest trees, of the *Pinus* family, found at Amboyna and in New Zealand. This was called *Pinus dammara* by Lambert, *Agathis loranthifolia* by Salisbury, but now a separate genus, as above. Rooted plants grow freely in sandy loam and moor-earth, but are very difficult to strike from cuttings.

**DAMPIERA** (Robert Brown). A New Holland genus named in honour of Captain W. Dampier, a celebrated navigator and botanist. It belongs to *Pentandria Monogynia*, and to the natural order *Goodenovicæ*. It is easily propagated by cuttings.

**DANDELION**, is the *Leontodon taraxacum* of botanists; and one of our most common and conspicuous British weeds. It annoys both the farmer on his arable land, and the gardener among his crops; to the latter it is a disgrace, if suffered to flower. Nature has done much for this plant, even the smallest portion of its root, forms a new plant, and its seeds, being furnished with a most elegant flying appendage, are transported far and wide by the wind. On the continent, the leaves, when blanched, are preferred to endive; and it is said that, when the roots are oven-dried and ground to powder, they are no bad substitute for coffee. Goats, sheep, hares, and rabbits, are fond of the leaves; but it is by no means a desirable plant either in meadows or pastures.

**DAPHNE** (Linnaeus). A rather extensive genus of highly ornamental shrubs, natives of many different countries, though chiefly European. Linnaean class and order *Octandria Monogynia*, and natural order *Thymelææ*. Generic character: calyx corolla-like, funnel-shaped, withering without, dropping off, four-cleft; stamens inserted in a double series on the tube; anthers roundish; style very short; stigma headed; drupe many-seeded. There are above twenty species of the genus, and many varieties, some of them exceedingly ornamental. Some are stove, others greenhouse, and the greater number hardy. A few

are propagated by layers and cuttings, but most are increased by grafting on the common wood-laurel (*D. laureola*), or on the mezereum. Some of the smaller sorts grow well in moor-earthly soil, prepared for American plants, but most of them thrive in any light soil.

**DAPHNIA** (Müller; *MONOCULUS*, Linnæus). A genus of small crustaceous animals belonging to the sub-class *Entomostracu*, order *Branchiopoda*, and section *Lophyropoda*. The body is of an oblong oval, and compressed form, evidently enclosed in a bivalve shell, attached to the skin, having its aperture beneath the body, and its hinge above the back. The head is distinct, and produced beneath into a kind of snout, furnished with a single central small eye. From each side of the head arises a large antenna-like organ, having a long basal joint, at the extremity of which each antenna is divided into two long articulated branches, each of which supports a number of long bristles. The functions of these organs in swimming, being, in fact, the only external apparatus employed in this motion, has induced M. Strans to regard them as forelegs, although it is evident, as Müller and Jurine observed, that they represent the upper antennæ of the typical crabs. And here we may take occasion to notice the great difficulty existing in the determination of the nomenclature of these and other organs, in groups of animals which recede so entirely from those which, by common consent, are considered as the types or normal divisions of the class—and, indeed, the remark is applicable in every other branch of the creation. We mention this subject because Dr. Johnston, the celebrated naturalist of Berwick-upon-Tweed, has recently published some observations bearing upon this view of the question in the Magazine of Natural History, which deserve attention.—Speaking of one of the species of the shark parasite, *Pandarus alatus*, he says: “The student who is anxious to see how ingeniously the few and simple organs of this creature can be analysed and resolved into parts corresponding with the complex organs of the crab and lobster, must consult the interesting memoir of Milne Edwards (in the *Dictionnaire des Sciences Naturelles*, vol. 28).” I must acknowledge that the analogies seem not a little imaginary, and the nomenclature derived from them is at least faulty, in so far that it gives, or is apt to give erroneous ideas relative to function; the feet-jaws are not subservient to mastication in any way; the animal is suctorial, and requires no jaws, and these organs are used solely to obtain fixedness of place, while the thoracic feet again are not organs to walk or creep on, but are only calculated for swimming, which, we can conceive, it may often have occasion to do. Although we admit to its full extent the soundness of Dr. Johnston’s remarks, in examining an animal *per se*; we certainly do feel, when investigating the same animal with reference to the structure of the remainder of its class, that the great difficulty with which the subject is surrounded ought to make us hesitate before we condemn a series of names which the strictest analogy has proved to be correct. Let us, however, look at the matter with reference to some of the better known examples of the class. Examine a lobster and a crab, and the mouth is found to be externally composed of several pairs of flattened organs, having a transverse motion, and evidently acting as jaws, whilst the large pair of fore legs is terminated by great and powerful claws. Now, examine a spiny lobster (which is not uncom-

monly to be met with in the fishmonger’s shop, belonging to the genus *Palinurus*), and the claws are no longer to be seen; in their stead a pair of limbs are found, having indeed the same number of joints as claw-legs, but formed like the following legs, and evidently being employed in locomotion. But will it be said that the least stretch is given to our fancy when we assert that the leg of the *Palinurus* is the claw of the lobster in a modified state of development, or that the former analogically represents the latter? Should we incur the chance of ridicule if we describe the claw of the lobster as a leg, although it be employed only in prehension, and not in locomotion?—Let us, however, now examine one of the little leaping shrimps, so common on the sea coast, and of which one species abounds in fresh water (*Gammarus pulex*), and we find the mouth deficient in a certain number of pairs of organs, but that the legs have obtained an increase of the same number of pairs; whilst the examination of such genera as *Sergestes*, *Sicyonia*, &c., clearly demonstrate the transition of structure and function from mouth organs to legs. Will it be said that we are adopting a faulty nomenclature, because we employ a term for these thus transitory organs, which indicates that they are liable to this singular kind of transition? We are aware that, by the unthinking, and by those who would lead the unthinking by the employment of arguments resting upon general and, as we may say, vulgar observation, rather than upon accurate but difficult analysis, we should be ridiculed in asserting that the sucker of the butterfly, and the under-jaws of a beetle, are the same organs in a different state of development, and in applying to both the same term; but we contend that the arguments which we have above brought forward are applicable to one case as well as the other; that there is no fanciful theory to be built upon this strict application of the rules of analysis and its consequent analogy, and that when, by the application of the former, and the adoption of the latter, we arrive with certainty (and here, as we said in the outset, lies the great difficulty) at the conclusion that a certain organ in one animal is the representative of an organ in another animal, we are at liberty in a strictly philosophic view of the subject to apply to both the same name, although in common parlance it is necessary, perhaps, to use different terms indicating the precise functions of each organ.

Within the shell of the *Daphnia* are to be observed ten small leg-like organs, having the second joint vesicular, the eight anterior ones being terminated by a dilated joint, margined with hairs, and serving as oars, the anterior pair appears, however, to be employed more especially in prehension; the posterior pair of legs is differently constructed. By a curious provision the eggs are deposited in a dorsal kind of pouch beneath the shell within which they are hatched; at the end of the fifth day the young have acquired sufficient power to take care of themselves, and are expelled by the female.

These animals, of which there are numerous species, are found in fresh and standing water, where they swim about with very great agility, their large branching antennæ giving them a curious appearance, hence they form interesting objects for the microscope.—Their history has been traced, notwithstanding their minute size, by several eminent observers, the works of Messrs. Schæffer, Ramdohr, Straus, and the elder Jurine may be especially mentioned. By Swammer-

dam, also, they were noticed under the name of *Pulex aquaticus arborescens*, the latter name being given to them in allusion to their branching antennæ. It has been observed as a remarkable circumstance, of which but few instances occur in nature, that a single impregnation is sufficient for several (six or more) generations. An analogous law occurs amongst the plant lice (APHIDES, which see). Occasionally these insects abound in stagnant water to such a degree as to impart to it their own tint; and as one of the species is of a red colour, the colour thus imparted to the water has been supposed to have been caused by blood.

The type of the genus is the species above mentioned, or the *Monoculus pulex* (Linnaeus). It is about one-twelfth of an inch long, and in spring is of a red colour, which towards the summer becomes rosy; but at other seasons it becomes of a greenish white colour. It is very abundant.

DARNEL, is the *Lolium temulentum* of Linnaeus, a species of grass too often found in autumn-sowed crops of corn. If its seeds, which are nearly as large as those of rye, are mixed with wheat, and made into flour therewith, it renders the bread bitter and unwholesome. Indeed, the plant is the dread of farmers, and the seeds are detested by the miller; nor is there any easy way of ridding the wheat of it, if thrashed together. Hand-picking the sheaves, as they pass through the hands of the binder and thrasher, is most effectual, because neither sieve, nor screen nor fanners, can separate the darnel from the wheat; and if a single grain of the former be seen in the sack at market, the value of the latter is very much reduced.

There are two old popular errors relative to this plant which are not entirely discredited at this day. The first is, that it is the plant whence the cultivated wheat was originally obtained, and that wheat may be grown till it all turns again to darnel! This is truly ridiculous; for, except being in the same natural order, no two plants can be more unlike in quality than the *Lolium temulentum* and the *Triticum hybernum*, or common wheat.

It is said to be sometimes used in the manufacture of low wines, for the purposes of the compounder of strong liquors; but this requires confirmation, as it is so strongly poisonous.

There is another grass which is sometimes confounded with darnel, because it is sown and reaped, and appears in the sample along with true darnel. This is the *Bromus secalinum*, a plant yielding seeds little inferior to small oats, and of fully as good quality. This last is called *ray*, and the other is called by its right name, *darnel*, though they are often mistaken for each other. The one is sweet and wholesome, the other bitter and stupefying.

DARTER—Anhinga.—A genus of web-footed birds belonging to the pelican family, and in many of their appearances and habits nearly allied to the cormorants. The species are not very well made out; but as the nearly allied genus of the cormorants is subject to considerable varieties of colour, both with age and with season, it is probable that the birds which have been noticed as differing a little from each other are all of the same species.

The species which is best known, if not the only species, is the white billed anhinga (*Plotus melanogaster*), which is found in the humid parts by the rivers, pools, and lagunes near the shores in the southern part of the United States, in Brazil, and

other parts of South America; and also on the humid parts of the west coast of Africa to the south of the desert.

Darter.

The length is about two feet ten inches; the wings long; the tail very long, the head and neck slender; the bill long and perfectly straight; the mandibles enlarged at the base, tapering to points at the tip, and finely serrated in the tomia; the upper mandible slightly channelled on each side; the nostrils linear in the channels, and concealed by a membrane; the tarsi short, but very thick and strong; all the toes webbed, the web of the hind toe joining the inner one as in the cormorant and all the birds which dash into the water for fish; the toes armed with crooked claws. The head is smooth, the colour of the belly white, all the other parts raven black, except a few mantlings of white on the tail.

It reposes on trees, where it also nestles, finds its food in the waters, and is rarely seen on the ground. When in a state of repose, the long neck is folded back upon the shoulders, and the bird stands upon the top of the tree rather than perches. Its perch or nest is seldom far from the water; and when the weather is very sultry, it may be often seen standing on a branch which projects over the water, and expanding and moving its wings and tail, as if producing a current of air to cool it. On these occasions it is said to contemplate its own image in the stream, but that wants confirmation, though many birds are known to be much interested with looking-glasses. If disturbed while thus fanning itself, it drops head foremost into the water as if shot, or rather struck by lightning, and instantly disappears, producing very little rippling, as its pointed bill, slender head and neck, and finely tapered shoulders, divide the water with the greatest ease. After a little time it ascends and shoots out of the water like an arrow at a considerable distance from the place at which it dived. At other times they fly high over the waters, and with powerful wing, darting down occasionally and capturing fish, which they do with great rapidity and certainty.

They are social birds, always found in packs, and sometimes in pretty numerous flocks; and though they are thus numerous in the same locality, they are generally fat, as they resort only to those places where they find plenty of food. They frequent only the perennial waters; they do not need to fatigue themselves by migrating from place to place. Their nests are rudely formed of sticks in the tops of the

trees, in a manner resembling those of the cormorants but as the places in which they build (often in the mangroves) are not very accessible on account of their swampiness, and as they are besides not a little pestilent, the family habits of the birds are not very well known. They are birds, however, which form a feature of the peculiar localities which they inhabit. They are not much disturbed, as their flesh is rank and bad.

**DARWINIA** (Rudge). A genus of two ornamental shrubs from New Holland. Linnæan class and order *Decandria Monogynia*, and natural order *Rhamneæ*. Generic character:—calyx like a tubular corolla, limb five cleft; corolla none; stamens very short, in a double series on the throat of the calyx; anthers oblong; style long and protruding. Easily propagated by cuttings.

**DASYCHIRA** (Hübner). A genus of lepidopterous insects, belonging to the family of Moths, *Arctidæ*, having the wings rather long, and the palpi very short and hairy. The spiral tongue is obliterated, and the fore legs very hairy; the caterpillars are very hairy, being furnished with pale tufts of hairs, which render them very conspicuous, and from which they have obtained the name of tussocks; the cocoon is of a close texture, having the hairs of which these tufts are composed worked into its meshes. There are two British species, the dark tussock (*Bombyx fascelina*, Linnæus), about two inches in expanse; and the pale tussock (*B. pudibunda*, Linnæus), a common species in the neighbourhood of London, rather larger than the preceding, having the wings of a whitish ash colour, the anterior pair having a central lunate spot, and three waved streaks of a brown colour. In Kent, the caterpillars are found in the hop gardens, and are called hop dogs.

**DASYPODA** (Latreille). A genus of hymenopterous insects, belonging to the section *Melifera*, and family *Andrenidæ*, or short-tongued bees. The species are of moderate size; the hind legs, especially in the females, are, as the generic name implies, very hairy, the basal joint of the tarsi being very long, and furnished with a complete brush of hairs; the wings have two complete sub-marginal cells; and the tongue is lance-shaped, and folded back upon the upper surface of the horny mentum. There is only one British species of this genus, and which was dedicated to Swammerdam by Mr. Kirby, in his History of the English Bees, in which work we find the following account of the habits of this pretty and interesting species:—"No person, at first sight, would take the male and the female of *M. Swammerdamella* for the same species, so widely do they differ in most particulars; nor should I have suspected that there was any connection between them, had I not discovered their retreat. In the month of August, 1797, I saw a female take her flight from a grassy declivity of a southern aspect, which was much entangled with roots and shrubs. Upon examining this spot more narrowly, I discovered a number of small burrows, each of which had a little heap of sand, which had been excavated from it, lying before it. In some of these burrows I saw our melitta (*Swammerdamella*) sitting, with her head at the mouth, enjoying the sunshine. At the same time I observed many other insects flying about the spot. Upon my attempting to take them, they disappeared, but they soon returned to their amusement. With some difficulty I at length succeeded in taking one,

and it proved to be the male."—Vol. i. p. 176. The body is of a black colour, clothed with pale fulvous or ochreous hairs, the abdomen of the female with three whitish belts, and the hind legs with orange hairs. It is rather a rare species; although occasionally met with in certain localities in some quantities. The food of the larvæ consists of pollen paste, stored up in cells by the female, which prefers the pollen of such flowers, as *Crepis*, *Haracium* and *Leontodon*.

**DASYPOGON** (Meigen). A genus of dipterous insects, belonging to the section *Tanystoma* and family *Asilidæ*. The body is long and thickened, often woolly; the antennæ are shorter than the head, with the terminal style distinct and conical, not terminated by a bristle, and the proboscis is straight.

This is an extensive exotic and European genus, forty-four European species having been described by Meigen; two only have, however, been found in this country; namely, *D. punctatus* (Fabricius), which is exceedingly rare; and *D. brevisrostris*, forming the type of Mr. Stephens' genus *Leptarthrus*, established upon the very slender form of the posterior tarsi in the males. This species is of a black colour, with the four posterior tibiae red at the base. We have met with it in the beginning of July, in some abundance, amongst grass, in the Devil's Ditch, on Newmarket Heath.

**DASYTES** (Paykull). A genus of coleopterous insects belonging to the section *Pentamera*, subsection *Serricornes*, and family *Melyridæ*, having the antennæ as long as the head and thorax, the body narrow and sometimes linear, the claws of the tarsi generally furnished with a membranous appendage, palpi filiform, and body destitute of the vesicular lobes visible in the *Malachiæ*. The name of the genus is of Greek extraction, and is given to these insects in consequence of the numerous hairs with which they are clothed. But little is known of the early history of these insects, which, in the perfect state, are generally found upon grass and umbelliferous flowers, in hedges, trees, &c. The species are numerous, and often prettily variegated in their colours; the indigenous species are of small size. Dejean, in his new Catalogue, gives seventy-four species, the majority of which are European and Brazilian. Stephens gives eight British species, of which the *D. caruleus* of Fabricius is one of the prettiest, being of a bright blue colour. It is about a quarter of an inch long, and is found on the southern coast. Some of the other species present various curious peculiarities of structure, such as the legs spined and twisted, the body quite linear, &c.

**DASYURUS** (rough and hairy tail) a genus of marsupial mammalia, peculiar to Australia, and in some of the species peculiar to the larger island, New Holland, and in others to Van Diemen's Land. It is worthy of inquiry what geological epoch of a country requires the presence of the marsupial or pouched mammalia in it; but the reasonable conjecture, from the fact of at least one marsupial animal being found in a fossil state in Europe, while within the period of history there has not been a living one found native nearer than America, would lead to the supposition that they are adapted for rather an early age, as respects the formation of the peculiar locality, if, according to what appears to be the most rational theory on the subject, we are to suppose that countries like their productions have a beginning, a duration, and an end; and that as they in all probability outlive races of animals, just as races outlive genera—

tions, the earth will be able to produce country after country, for a succession of changes, of the term of whose performance we can frame no conjecture, before the powers of the globe become unfit for the production of another new land; and so the ages of its duration are at last numbered, and it is by some great power, which is still an instrument in the hands of its maker, scattered in viewless atoms through the regions of space. This is a subject of great interest as well as curiosity, to which we shall briefly revert in the article *Marsupialia*, and more at large in the general article *Mammalia*, so that we must in the mean time confine ourselves to a very short notice of the genus, of which the systematic name stands at the head of this article.

The animals of this genus, some of which are however but imperfectly known, are almost, if not altogether, the only carnivorous mammalia of the extensive countries in which alone they are found; for there is little doubt that the *dingo*, or wild dog, (which, however, may be said to be in a state of domestication, bearing the same relation to the domestication of the dog in Europe, as the state of the native of Australia bears to European civilisation), the *dingo* is, probably, nay certainly, an importation by the Malays, which have long resorted to the north-eastern parts of New Holland to fish for *trepang* (*Holothuria*), for the supply of the Chinese market.

It is a remarkable fact that the carnivorous animals of Australia should be more so than the marsupial animals of other countries, while animals that are wholly herbivorous are also in the same country furnished with similar appendages. But though the fact is striking, we are not in the present state of our knowledge able to deduce from it any conclusion which enables us to connect any thing in the physical geography of Australia, which peculiarly adapts it to the habits of those pouched animals. We cannot let slip this first opportunity which has occurred in the order of alphabetical arrangement of noticing these singular animals, which unite indications of a physiological nature more than any other class of animals, without mentioning how desirable it would be to pay somewhat more attention than is usually paid to those circumstances, of a nature bearing upon both (of course) which link peculiar animals to their peculiar localities. In many instances, there is no doubt that the abundance of its most favourite food which the locality affords, has a very considerable influence in determining the animal towards that locality; but this can hold true only in the case of migrant animals, and will not apply to such genera as that under consideration, which have no means of crossing the sea by which their country is surrounded. The genus *Dasyurus* must be a native of Australia; and what is more, as there are some which are met with in the smaller island only, and some only in the greater, and as the differences between these are of too decided a character for our admitting the possibility of the one being a climatal variety of the other; and, further, as there has been no artificial training calculated in the least to change either one or other of them, the question becomes one of still greater interest to every one who would wish to obtain a solution of the most interesting problem in the whole range of national history—why animals should, in their physiological structure, differ from each other?—why should almost the whole of the native mammalia of Australia bring forward their young by a double gestation, the one in

an internal uterus, and the other in an abdominal pouch, while in Southern Africa, the latitude of which is the same and the climate not very dissimilar, there is not a single animal having even a fundamental vestige of this double gestation.

The genus *Dasyurus* has been, by various naturalists, divided into several genera; but as there are very strong resemblances between them all, we shall include our brief notices of them all in one article. Indeed, there is a characteristic physiognomy which runs through the whole of the marsupial animals, whatever may be the character of their food, their habits, their size, and even the forms of their bodies, which shows them to be a race actually belonging to a different system, and apparently a different epoch, from the common placental mammalia, of one internal gestation. Whether their fur be rough or smooth, it does not appear of the same texture as that of our mammalia; and there is, generally speaking, a ruggedness in their appearance, and a want of speculation in their expression, which makes them look as if they were not at home in the present period of the world's history, and did not form an appropriate part of its economy.

Their generic characters are: six grinders or cheek teeth in each jaw, of which the two anterior ones are compressed and trenchant, and the remaining four tuberculous, resembling those of insectivorous mammalia; their incisive teeth are small in size, eight in the upper jaw, and six in the under; and they are furnished with four canines; but the teeth altogether have a ragged appearance compared with those of the placental carnivora, and at the same time there is an apparent want of vigour in the jaws. They have on all the feet five toes, which are long, and very distinct in their phalanges, and armed with crooked claws, with the exception of the thumbs on the hind feet, which are little else than rudimental, and without any claws. The last phalange of the hind toes is furnished with a tuft of long hair, which extends forwards, and covers the claws. Sexually, the male agree with the opossums in the bifurcation of the organ, and in some other particulars, and there is that air of correspondence which we have remarked, as being characteristic of all the marsupialia; but they are without the climbing feet of the opossums, which, from the reversed thumb, are enabled to take hold of branches much in the same manner as the *ai-ai*. The ears are rather short and covered with hair; the tail is long and hairy, generally thick at its insertion, and in some of the species it is compressed laterally; but it is not prehensile in any of the species, neither are any of them capable of climbing for their food. They live much in concealment, and resemble in their habits the fox and the polecat, more than they do any other of the mammalia of Europe. They are all ravenous in proportion to their size; but their food varies considerably. The structure of their cheek teeth shows that they all can subsist upon insects; and it is probable that these constitute the principal food of the smaller ones. But those which are of more formidable size prey upon the smaller kangaroos, the ornithorhynchus, and bats, which are very numerous in some parts of the country. They also prey along the shores, eating indiscriminately mollusca, fish, and any carrion or garbage however putrid. They are also said to plunder the poultry yards of the colonists in waste places, and also to destroy lambs. Their dispositions are bad, but even the largest of them have not courage in pro-

portion to their strength, and it is doubtful if they ever incline to attack the large kangaroo, or even the emu, unless they can come upon it by stealth; the colonists have given them the names of those European and other animals to which they fancied they had the greatest resemblance, such as cats, wolves, hyænas, leopards, and other names; but there does not appear to be a single native animal, or any one of those genera, in the whole of Australia.

There are at least eight species of the genus, three of which are natives of Van Diemen's Land, and the other five of New Holland; but it is probable that as the latter country becomes better known, more species may be discovered.

*Dasyurus cynocephalus*. This species is of Van Diemen's Land, and it differs so much from the others in some of its characters, that it has been made a separate genus under the name of *Thylacinus*. It is an animal of considerable size, being about three feet and a half in length, exclusive of the tail, which measures about two feet. It stands one foot one at the shoulder, and one foot eleven at the rump,—the marsupial animals being almost, without exception, higher and more stoutly made in their hinder parts than forwards, which forms a very distinguishing character between them and the generality of animals which are not marsupial.

The tail of this species is very peculiar, and different from that of all the others of the genus, being compressed or flattened sideways. The covering of the animal is smooth and short, of a dull yellowish brown in the ground colour, paler on the under part, and mixed with grey on the back; and across the loins and rump there are six or seven transverse bands of black, two of which extend down the thighs. This animal squats on its hams in the attitude of a dog, but its expression is dull and stupid, and it has neither the sagacity nor the activity of the predatory animals of Europe. It is generally found near the shores, and lodges in deep caverns and clefts of the rocks, so that it is not often seen in proportion to its numbers.

*Dasyurus ursinus*. This is also a native of Van Diemen's Land, and not found, so far as is known, in the larger island. It is smaller than the former species, and different in all its characters and habits, so that the generic distinctions between them appear to be correct; and it is probable that, when they come to be better understood, it may be necessary to subdivide them into more than two genera, though they will still require to be kept together as a very natural group.

The present species is about two feet and a half long, and the tail about nine inches, and unlike that of the last species, it is naked on the under side, and slightly prehensile. The whole body and upper part of the tail are covered with shaggy black hair, marked on the back with a few obscure white blotches. It is in consequence of this rough covering that it gets the name of the bear; and its peculiarly repulsive aspect has procured it from the woodsmen of Van Diemen's Land, who are not over chary in their vocabulary, the name of "the Devil." Its manners, like those of most of the genus, are very little known; it lives in obscurity, and though, from the character of its teeth, which are the same as those of the former, it in all probability feeds a good deal upon insects, reptiles, and its fellow-lodgers the bats, yet it is said to range more extensively, to be more fierce and daring, and to commit greater depredations upon poultry and lambs than

the former one; still, however, when seen, for that is not often, as it is in the depths of caves during the day, it is near the shore, and very generally close by the margin of the waters.

It is worthy of a passing remark, as throwing some light upon the natural state of Australia, and this is a subject to which much attention should be paid, because we are in possession of its history, clearly and fully from the very first time that a sod of it was broken by the spade, that both the human inhabitants and the predatory animals of this part of the world were found only on the margin of the waters, chiefly on the sea-shore, but also, at least seasonally, on the banks of the rivers, and that the chief subsistence of both was fish, and at some seasons of the year shelled mollusca. This may, perhaps, account for the very small number of even these species of predatory animals in regions so extensive, and also for the extirpation of them from the larger island, supposing them once to have been found there, at least it is a remarkable instance of man and the predatory animals being rivals for the very same food in the very same localities; and we may naturally suppose that rude as were the aborigines of these countries they would exert themselves to extirpate the dasyuri with the same assiduity that the wolf and the fox have been hunted down in Europe, and the former extirpated in many parts of it. The wars of wild men against wild animals, would not only be an exceedingly curious subject in itself, but if it were properly studied it would throw considerable light upon the progressive history, at least, of the predatory part of the animal kingdom.

*Dasyurus minimus*. This is also described as a native of Van Diemen's Land, and has been much more readily met with than either of the other two. It is a very small animal, not above four inches in length, and the tail short, with very short hair, the fur on the body is soft to the touch, and reddish at the points. Its head is conical, and its muzzle very small. Altogether it has fully as much resemblance to the opossum as to the other members of this group. Very little, however, is known of its history.

*Dasyurus macrourus*. This species is found in New Holland, and was for some time described as belonging to the weasel family, and named as such by Shaw who was long employed in the naming of beasts, though sometimes not very happily; but then the fault was not his, as he had only the skin to name them from, and of course had no means of judging of their structure, or assigning them a place in the system, in accordance with their nature. This species is styled the spotted marten, and sometimes the wild cat by the colonists, which has led those who make up works from popular sayings, without having the means of ascertaining their truth, to include the cat among the native animals of Australia, though there is no reason to believe that there is a single individual of the feline group indigenous to the country.

This species is about a foot and a half long, with a tail nearly the same length. Its fur is very thick, and soft to the touch, the colour otter brown, relieved with spots of pure white, which are very small on the back, but yet larger on the sides, and the belly is entirely white. The head is maroon red, and the feet yellowish. The two incisive teeth in the middle are more produced than the others, which gives the mouth of the animal a ragged appearance. This is a nocturnal animal,

There is some obscurity about the distinctions of the other species, as it is doubtful whether some of them which have been described from single specimens may not be the young of the one under consideration. The investigation of those disputed points could have little interest for the general reader, and therefore we must refer such as are anxious to be better acquainted with the carnivorous mammalia of Australia, to the systematic works; and, from the zeal and ability of many of those who are now investigating the natural history of the colony in all its departments, we have no doubt that information will soon be obtained which will be highly satisfactory; and, therefore, it would be ill-judged on our part to hazard conjecture while in expectation of the truth.

DATE PALM is the *Phoenix dactylifera* of Linnæus. This is one of the most useful of the palms, it yielding every year great crops of fine rich fruit, forming not only a valuable part of the food of the lower orders of society, but a vast surplus for exportation to other countries.

Persia, Palestine, and the northern states of Africa appear to be the most congenial climates for the successful culture and growth of the date tree. In some of those countries there are extensive groves of them, furnishing employment and wealth to the generally indolent natives. The stem is not so lofty as some of the other palms, but it is comparatively much thicker and very rugged from the persisting bases of the fallen fronds. When the fruit are ripe, they are shaken from the pendent spadix by one man, while others hold a cloth, extended below, to receive the falling fruit. These are afterwards sorted and prepared for packing in jars or boxes for sale.

Young date trees may be raised from the stones of the imported fruit; and as they have much divided and persisting foliage, they add an interesting variety to the stove collection. If planted in a tropical conservatory, and allowed time and space, there is no doubt but they would flower and fruit in this country, which would, at least, be a great curiosity to British botanists.

DATISCEÆ. A natural order of dicotyledonous plants containing only a few genera and species. In its habit and the structure of its fruit, it bears a close resemblance to *Acetaceæ*, and seems to be a connecting link between that order and *Urticææ*. Its essential characters are: flowers diœcious; perianth of the male flowers divided into several pieces, that of the females free, toothed; stamens several; anthers two-celled, membranous, linear, bursting longitudinally; ovary one-celled, with polyspermous parietal placentas; stigmas equal in number to the placentas, recurved; fruit capsular, opening at the top, one-celled, with polyspermous parietal placentas; seeds enveloped in a membranous, finely reticulated integument; embryo straight, without albumen, its radicle turned towards the hilum.

The plants belonging to this order are strong hardy herbs, with alternate compound leaves without stipules, and axillary racemose flowers. From their resemblance to hemp, some of them receive the name of bastard hemp.

They are found in the northern parts of America and Asia, as well as in the Indian Archipelago, and the southern countries of Europe.

Their properties, so far as known, are bitter and tonic.

The chief genera are *Datisca* and *Tetrameles*.

DATURA (Linnæus). A genus of herbaceous annuals, natives of many foreign countries, one of which the *D. stramonium* has become naturalised and grows wild in England. They generally bear large white or purple flowers, but are of a short duration. They belong to the fifth class of Linnæus, and to the natural order *Solanææ*. Seeds.

DAUBENTONIA (Decandolle). South American evergreen shrubs, belonging to *Diadelphica Decandria*, and natural order *Leguminosæ*. Generic character:—calyx bell-shaped, five-toothed; keel obtuse; pod on a footstalk; linear, with four longitudinal wings; pod contracted between the seeds. This genus has been consecutively called *Piscidia*, *Robinia*, *Aschynomene*, till settled by Decandolle as above. These plants thrive in loam and moor-earth, and are easily propagated by cuttings in the usual manner.

DAUCUS (Linnæus). Is the generic name given to the family to which the common carrot belongs. The genus ranks in the fifth class and second order of the sexual system, and in the natural order *Umbelliferaæ*. Some few are annuals, but they are mostly biennials: of all our cultivated culinary vegetables, no one shows the effects of domestication more decidedly than the carrot. It is found wild on every dry hedge-bank, every where in Britain, as well as on the continent. In its wild state, it is a diminutive plant, with an underground stem, no bigger than a small radish. In former times the daucus was held in high estimation as a medicine; a decoction of it being considered useful as a diuretic, or solvent of the human calculus. It might be at first introduced into the garden of the herbalist for its medical properties only, and there showing a tendency to increase in bulk, might be in the course of time removed from the simpler's shop to the green larder of the cook.

The improvement of the plant in bulk must have been gradually accomplished. It is unreasonable to suppose that a wild plant would suddenly, in any season or in any place, swell from a mere stick to a portly tuber at once.

How or when it became a culinary plant is, perhaps, not now known; but looking at the wild one in its native bank, and on the full-grown Altringham variety on the green grocer's stall, we are compelled to acknowledge that there is not a stronger proof of the ameliorating effects of culture exemplified in the whole range of vegetation.

And it is not only an improved bulk of the common wild plant that has been the only result of skill and industry, many varieties have been originated by attentive cultivators; so that there are large and late sorts for feeding cattle, and small, early, and more delicately flavoured sorts for the table; in all fifteen varieties, differing in size, colour, shape, or earliness.

Cultivation. As carrots may be used at any stage of their growth, and as they are most tender when young, seed is sown at many different seasons. The first sowing may be made about the twentieth of February; but this sowing should occupy only one or two narrow beds on a dry, finely-digged, south border. Here the seedlings may be forwarded and protected from the keen winds of March by a thin covering of dry fern leaves or peat-straw; and in order that such covering may not harbour slugs, snails, and worms, it should be from time to time dusted with hot lime, which will save the seedlings from destruction. Carrots are also sowed about the same time on

slight hotbeds and under glazed frames, to get them ready for table as early in the year as possible.

The principal crop of carrots either in the garden or fields may be sowed any time between the twentieth day of March and the tenth of April; and successive sowings should be made in every month till September. This is, however, only necessary where young carrots are constantly required in every month of the year.

The seed requires to be prepared for sowing by being well rubbed between the hands until divested of the fringe of little hooks with which they are invested when gathered; otherwise they cling to each other so closely, that they cannot be equally distributed by the sower. When prepared, the seeds may be sowed either in shallow drills one foot apart, or broad-cast on beds three and a half feet wide with alleys between. Whichever way the seeds are sown the plants will require to be thinned to eight-inch distances apart either by hand or hoe. This thinning is usually performed in dry weather, and when the plants are two or three inches high. When this is done the crop only requires to be kept free from weeds during summer, and until fit to be taken up for storing.

Carrots are usually taken from the ground about the end of October. A dry day is most suitable, because the tubers are easier freed from the earth; and being sorted and topped, and quite dry, are then stored in sand in a dry shed or hovel for winter and spring use.

Carrots thrive best in deep sandy loam, and are larger or smaller, according as this is rich or poor. Their form indicates that a deep loose soil is requisite; and, therefore, deep digging or trenching the ground intended for carrots is indispensably necessary. It is not customary to dung for this crop; because if not trenched in very deep, the tubers are liable to be deformed, becoming forked rather than straight. The roots are liable to be disfigured by the larva of an insect which eats into the rind; this defect occurs mostly in old garden ground; and more especially to the crops sowed in March. If sowed on fresh loamy land they suffer less from the worm; and the sowings made in April and May are not eaten so much as the early crops.

The garden varieties of carrot are as follow:—

Early Horn, Long Orange, Fine Surrey,  
Scarlet Horn, Short Orange, Altringham.

There are also three or four other varieties named from places where they are most successfully cultivated. But the early horn is always chosen for the first crops, whether on hot beds, or in the open ground, and also for the last sowings in August and September; and which latter, if they gain any useable size, require covering from frost. For principal crops in gardens or fields, the long orange and Altringham are preferred, because of their larger growth and fitness for farming purposes.

Some cottagers, and even professional gardeners who are situate on stiff-clayed soils, are obliged to have recourse to a peculiar mode of culture, in order to procure large and handsome carrots. On the ground intended for them, ranks of holes are made by line with an iron-shod taper dibber, fifteen inches in length; the holes are filled with fine rich compost, and on the surface of each two or three seeds are dropped and slightly covered. When the plants have risen out of harm's way, one only is left in each

hole to grow to perfection. The leading radicle finds a free course downwards, and the whole root necessarily receives a fine form, and arrives at considerable magnitude.

**DAVIESIA** (Smith). A genus of New Holland evergreen shrubs, Linnean class and order *Decandria Monogynia*, and natural order *Leguminosæ*. Generic character: calyx bracteate, bell-turbinate, five-toothed. Corolla, vexillum inversely-heart-shaped, erectly reflexed. Keel having short wings. Style straight and persisting. Pod compressed, one-seeded, lower suture dilated, and somewhat trapezium-shaped. These pretty plants thrive well in our green-houses potted in loam and moor-earth, and are propagated by cuttings struck in sand under a hand-glass and without bottom heat.

**DAY LILY**. Is the genus *Hemerocallis* of Linneus and other botanists. They (the four species) are hardy, herbaceous plants of rank growth, and suitable for borders of shrubberies, and among plants of tall growth.

**DEADLY CARROT**. Is the *Thapsia villosa* of Linneus, an umbelliferous genus, found in the south of Europe, two species of which are considered highly poisonous.

**DEADLY NIGHTSHADE**. Is the *Atropa Belladonna* of Linneus. It belongs to *Pentandria Monogynia*, and to the natural order *Solanææ*. It is a strong growing plant, with large ovate leaves, purple bell-shaped flowers, succeeded by dark-red coloured berries, as large as small cherries. The plant is often found growing in rubbish of old buildings, and on waste ground about farm-houses.

**DEAD NETTLE**. Is the *Galeobdolon luteum* of Smith, a common British plant found in moist, shady places: it receives its name from its resemblance to a nettle, but without its stinging property.

**DEATH'S-HEAD MOTH**. The largest species of lepidopterous insects found in England, and systematically known by the name of *Acherontia atropos*. By Linneus, indeed, it was placed in the genus *Sphinx*, but as it differs in several material points from the majority of the insects of which that genus is composed, Ochsenheimer, a German lepidopterist, separated it under the generic, or rather, perhaps, subgeneric name of *Acherontia*. The specific name *Atropos* (the third of the fates in the heathen mythology, who was supposed to cut the thread of life,) is given to it in reference to the very peculiar markings upon the back of the thorax, which, as the English name indicates, very closely resembles a skull or death's-head. And here we may be allowed to notice the admirable plan introduced by Linneus of giving to each distinct species of animal, a name, consisting of a single word, whereby in general, some peculiarity of the creature is indicated. Before the introduction of this system it was necessary, in mentioning any animal, to give a short description of it, as for instance, of the insect in question, it would have been necessary to speak of the "*Acherontia atropos*" as "a large moth having a skull marked upon the back." Whereas by the concise and elegant terms invented by Linneus, all this circumlocution is avoided, and by the employment of a generic and a single specific word, the animal is known through the whole of the scientific world.

The Death's-head moth measures from four to five inches in expanse, the fore wings are of a dark brown colour, variegated with grey, brown, and black, with a white central spot; the hind wings are clay-coloured

with two dentate black fascia; the abdomen, which is very robust, is also clay-coloured with black bands, and a black central dorsal line. The thorax is blackish grey, with a large central, pale, irregular

Death's head Moth.

patch, in which are two round black spots. "This grand species," observes Mr. Haworth, *Lepidoptera Britannica*, p. 56, "is at once the largest and the only one as yet discovered of this order of insects which is endowed with the powers of voice, almost every individual of the insect world, the hymenopterous part excepted, is mute. My tutor in entomology once had a male and female of *A. atropos* brought him alive in the winged state, both of which, when he had occasion to destroy them, uttered plaintive sounds, which he compared to the squeaking of a mouse." He then proceeds to give an account of the various sounds produced by insects, all of which we may observe are not caused, as in the vertebrated animals, by the aid of air which is respired, but by some external apparatus designed for such particular purpose. The cry of the Death's-head moth does not appear however (as Messrs. Kirby and Spence observe) to be produced by the wings, for when they as well as the thorax and abdomen are held down, the cries of the insect become still louder; according to Schroeter, the noise is accompanied by the rubbing of the tongue against the head,—whilst Roesel considers that it is produced by the friction of the head and thorax. Reaumur, however, thought it was caused by the friction of the tongue against the palpi, as he found that it ceased when the tongue was unfolded by the assistance of a pin; as was also the case when the palpi were prevented from touching it: so also, on cutting off one of the palpi, the noise became more feeble. M. Passerini, however, has lately investigated the subject anatomically, and traced the origin of the sound to the interior of the head, in which he discovered a cavity at the passage into which the muscles are placed for impelling and expelling air; the cause, as he thinks, of the sound in question. M. Dumeril has since discovered a sort of tympanum stretched over the cavity, like, as he says, to the head of a drum (*tendue comme la peau d'un tambour*). Other opinions have been given by Messrs. Lorry and Duponchel, for which we must refer to Mr. Stephens' invaluable work, vol. 1, p. 117. The caterpillar of this insect, also, if alarmed, draws suddenly back, making at the same time a rather loud noise, somewhat like the crack of an electric spark.

Our readers will not require to be reminded of the numerous instances in which the accidental appearance of insects in more than ordinary numbers has been regarded by the vulgar with astonishment and alarm: hence it is not surprising that the sudden visitation of the Death's-head moth should be regarded as ominous and as the forerunner of death. Latreille, (*Hist. Nat.* 14, 128,) tells us that it appeared one year

in Brittany in great numbers, and as at this period an epidemic malady was raging with much violence, the mortality was attributed by the ignorant to the harmless moth.

Another peculiarity connected with the history of this moth, consists in its attacking bee-hives, ravaging the honey, and dispersing the inhabitants. It is singular that a creature, with only the advantage of size, should dare, without sting or shield, singly to attack in their strongholds a people so numerous and so well armed with means of defence; and still more singular that, amongst so many thousands of bees, it should always contend victoriously. Huber, who first noticed this circumstance, thus reasons upon the subject.—"A moth is the dread of superstitious people, may it not also exercise a secret influence over insects, and have the faculty either by sound or some other means of paralyzing their courage. May not such sounds as inspire the vulgar with dread, be also the dread of bees." The same author states, that he was eye-witness of the curious fact that the bees, as if expecting their enemy had barricaded themselves by means of a thick wall of propolis and wax, completely obstructing the entrance of the hive, but penetrated by passages for one or two workers at a time, thus securing themselves, by an admirable sagacity, against the inefficiency of their weapons and their courage. "The art of warfare amongst bees," he adds, "is, therefore, not restricted to attacking their enemies; they know also how to construct ramparts as shelter from their enterprises, from the part of simple soldiers they pass to engineers," instructing us that at the season when the moth appears, when too wasps and bees attack the hive, it is advantageous to narrow the entrances to the hive, so as to prevent the depredations of these obnoxious insects.

The moth appears in the winged state at the close of the autumn, the caterpillar being full fed at the end of September, and a very few weeks only being required to bring the moth to perfection. The caterpillar is very large and handsome, being of a pale greenish yellow colour spotted with black, with several lateral oblique stripes of beautiful blue and green. It feeds upon the potato, as well as occasionally on the jasmine, artfully concealing itself in the day time on such parts of the stems of the plants as are best covered with overshadowing leaves, but although they feed well, and complete their transformation to chrysalis, it is difficult to obtain them in the winged state, generally dying during their pupation. "Perhaps," observes Mr. Haworth, "in a state of nature they perform their extraordinary metamorphoses deeper in the ground, and consequently in a moister and more equal temperature than most other species of *Lepidoptera*; and, if so, the cause of their perishing in our breeding cages is, undoubtedly, owing to their having in these cages too scanty and too dry a soil." We have known specimens obtained in the winged state, by placing them upon potatoes growing in pots in the open air, plunged into the earth, and the plant covered with gauze. The caterpillar has a curious horn upon the back, near the extremity of the body.

**DEATH WATCH.** A small coleopterous insect belonging to the section *Pentamera*, family *Ptinidae*, and genus *Anobium*, which lives in timber and wood-work, and makes a slight noise, somewhat like the ticking of a watch. As in the Death's-head moth, we have here an instance of that lamentable proneness amongst the vulgar and uneducated, for investing the

most simple and harmless objects with the most fearful powers. Swammerdam, speaking of this insect, says, "I have likewise the small beetle, which having firmly and strongly fixed its foremost legs, and bent and put its head through the space between them, makes a continued noise in old pieces of wood, walls and ceilings, which is sometimes so loud that upon hearing it people have been persuaded that nocturnal hobgoblins, ghosts and fairies wandered about them. I think that this may be properly called *Soniccephalus*, or the noisy-headed beetle." Hereon we may observe that Swammerdam's countrymen, the Dutch, do not from his account appear to be so far gone in superstition as the English, by whom this noise is considered ominous of death. Thus Gay, in one of his pastoral dirges, says—

The wether's bell  
Before the drooping flock toll'd forth her knell,  
The solemn death-watch clicked the hour she died.

And Swift thus satirically alluded to the same insect :

A wood worm,  
That lies in old wood, like a hare in her form,  
With teeth or with claws it will bite or will scratch,  
And chambermaids christen this worm a *Death-watch*;  
Because, like a watch, it always cries click;  
'Then wee be to those in the house who are sick,  
For sure as a gun they will give up the ghost,  
If the maggot cries click when it scratches the post.

The insect, generally considered as the real death-watch, and of which various figures have been published in popular works upon natural history, is the *Anobium tessellatum*, having the wing-covers of a dark brown colour, spotted with tessellated markings. This species, however, is found in old standing trees; whereas it is evident that the insect in question must be one which feeds in-doors upon timber worked up into articles of furniture. At the present time (the beginning of July), clicking is to be distinctly heard upon the ceiling and window-frames of houses in the country produced by various specimens of this insect (which we have figured from living specimens), and which is of a much smaller size, and more uniform colour than the preceding, being the *Anobium striatum*. This noise has been considered to be the call or signal by which the sexes are mutually attracted to each other, and as analogous to the call of birds. The general number of successive distinct strokes is from nine to eleven, given in pretty quick succession, and repeated at uncertain intervals; and in old houses, where the insects are numerous, they may be heard during the warm weather almost every hour of the day. The noise exactly resembles that made by beating moderately hard with the finger on a table, or rather, we should say, to scratching the top of a chip-box with the point of a pin. Mr. Stackhouse long ago observed the manner in which the noise is produced. The insect raises itself upon its hinder legs, and, with the body somewhat inclined, beats its head with great force and agility against the place on which it stands. On disturbing it, the head is drawn close to the front of the thorax, so as to have the forehead quite perpendicular; the legs are folded up, and the antennæ lodged in recesses between the head and thorax, so as to be quite imperceptible. From these, and other recorded observations, it is evident that, in its perfect state, the insect makes this ticking noise, and also that the noise is produced when the insect is at large. We

have, however, more constantly heard the noise in the interior of wood-work, and it has hence appeared more than probable that the noise (and it is now frequently to be heard within the wood, when the insects are arriving at their beetle state) is caused by the newly-hatched beetle eating its way through the wood to arrive at the daylight. The metamorphosis of the anobia take place near the surface, the larva taking the precaution of making its way so close to the surface, that only a very little space remains for the perfect anobia to bore through. Hence we infer that the noise is produced by the action of the jaws of the beetle upon the wood, and in this manner only can we account for the fact of the ticking being heard (see Mag. Nat. History, September, 1834) throughout the winter, at a time when the insect is in the larva state, the larva itself also producing the same noise by the similar action of its powerful jaws, in gnawing away the wood, so as to leave but a feeble barrier through which the perfect insect can pierce with facility. Olivier indeed supposes that it is for the purpose of ascertaining the thickness of this barrier that the noise is occasioned. We, however, would refer it to the simple action of gnawing, which, of course, is applicable both to the larva and perfect states. There are not fewer than eleven species of beetles described by Stephens as belonging to the genus *Anobium*, and it is probable that the majority possess the same powers of making the ticking noise above described; but it is evident that the true death-watch must be that species which resides in old wood furniture, and which we have figured beneath.

Death Watch, natural size and magnified.

There is also another insect common in old wood furniture, books, &c., both sexes of which have the power of making a ticking noise, but not so loud as the others. This is the *Atropos lignarius*, for an account of which see our article *ATROPOS*.

**DECACERA.** In the arrangement of modern malacology constituted the second family of the first order *Cryptodibranchiata*; first class, *Cephalophora*, including the genera *Loligo* and *Sepia*.

**DECAPODA**—Ten-legged. An order of crustaceous animals, comprising all the larger species of the class, and well characterised in having ten legs; the head intimately united with the thorax, and covered by a large shell or shield; a mouth, consisting of numerous pairs of organs, of which the outer pairs, in some of the species are elongated; but the most characteristic trait consists in the existence of gills or branchiæ, more or less numerous, fixed in a peculiar cavity beneath the sides of the shell.

This order is divided into two sections, namely, the *Brachyura*, having the abdomen shorter than the thorax, beneath which it is folded in repose, and not furnished with a terminal fan-like tail: the common crab is an example of the first section; and second the *Macroura* having the abdomen longer than the

thorax, beneath which it is not folded at rest, and is furnished with a fan-like tail. The lobster, prawn, &c. are examples of this section. See also *Crustacea* and *Brachyura*.

**DECIDUOUS CYPRESS.** Is the *Schubertia disticha* of Mirbel, the *Taxodium distichum* of Richard, and *Cupressus disticha* of Linnæus. Richard's name is most generally adopted. It is one of our most beautiful deciduous forest trees.

**DECUMARIA** (Linnæus). A genus of North American twining shrubs, belonging to *Dodecandria Monogynia*, and to the natural order *Myrtaceæ*. Generic character: calyx bell-shaped, limb of from seven to ten teeth. Corolla consisting of from seven to ten oblong petals. Stamens numerous, filaments filiform, anthers twinned: style cylindrical; stigma a many rayed head; capsule valveless, many-celled, seeds oblong. This plant is used in gardens for covering trellises or naked walls, grows in any soil, and is propagated by cuttings.

**DEER**—*Cervus*. A genus of ruminant mammalia, having solid horns, which consist entirely of bone, without any case or sheathing of horny matter; so that, though they are the most largely developed and splendid head-gear in the whole of the animal kingdom, they are in truth not horns but bones, covered in their early stage with skin and hair, exposed when they come to maturity, and ultimately healed off at the close of the season; the peduncle to which the horn is attached being a complete cicatrix, and not a sore, and it soon skins over, under which skin a new horn begins to sprout soon after the old one is shed, comes to maturity, and is shed again; and so on during the life of the animal.

These annual horns belong only to the male in most of the species; but in the rein-deer the female also is furnished with horns, only smaller than those of the other sex. The case of this species supplies us with a physiological fact, from which we can form a pretty accurate judgment of the connection which this immense annual production of horns, that is of the matter of bone, has with the general economy of the animals. The horns of the two sexes come to full maturity at nearly the same time, that is, as the pairing time approaches, or the "rutting time" as it is called in the case of animals of this genus. As soon as this important period in the economy of the animals is over, the horns of the male begin to loosen at their bases, which they do first at the circumference, and gradually inward, till they drop off. The horns of the female again remain the whole of the winter, and do not drop off until her grand labour in the continuation of the race is accomplished—that is, not till after she has dropt her fawns. What purpose these horns may answer in the economy of generation, it is not easy to say; but as they continue in the male only till pairing, and in the female during the whole period of gestation, and as they drop off in both as soon as these great labours of the year is over, it is evident that they have some connexion with the sexual system of both, and that in the female this connection is with the uterine, and not with the mammary system.

In all the *ruminata*, as will be more particularly explained in our general article upon that most valuable class of animals, there seems to be a much greater concentration of the energy of the animal upon the time, the act, and the progress of reproduction, than there is in many other races, though we find it more or less in most of those which are exclusively vege-

table feeders, and it always becomes less and less as the animals become more carnivorous. Though we might expect this, it is so important a fact in physiology, that we shall offer a passing remark upon it.—All the grazing, or vegetable feeding animals, have labour in the procuring of their food, and those which browse the thin herbage upon the thirsty plains have considerable labour; and, therefore, they are compactly made, clean limbed, and fleet-footed. But not one of them requires to take its food by force or effort, to chase it as the dog does, or spring upon it as the cat. The food being fixed to the ground is peaceably taken; and, therefore, the general habit of the animal is not a habit of excitement. Unless, therefore, the animal lives under the exciting heat of an inter-tropical climate, we can hardly suppose that there would be sufficient excitement in it to bring it up to a degree of energy required for nature's greatest work. On the other hand, the carnivorous animal is kept in a state of constant excitement, in watching for, in coursing, in capturing, and very often in fighting severely before it overcomes that upon which it feeds; and, besides this, the food of the carnivorous animal is more stimulating than the grass, the green leaves, the withered branches, the bark, and, in the case of some the present genus, the dry lichen, upon which the ruminantia feed. It should seem, therefore, that a means is required of keeping up throughout the year, a portion at least of this energy which requires to be called forth at one period of it; and the elaboration of horns appears to be the means by which this energy is kept up in the genus *Cervus*.

This genus affords many other confirmations of this, in the different productions of the appendages of the head—to which, by the way, it is better to give the name of *antlers* than of horns, even though the antler is strictly speaking the "brow snag" of the horn; *attire* is the hunter's name for them. In proportion as they inhabit near the equator, the horns are small; and as we come toward the polar countries they increase in size, and acquire their maximum in the extreme north, where a single pair of horns of the American elk, or moose deer, often weigh as much as sixty pounds. In the south, too, the females never have any horns, nor even in the polar countries till we come to the very last species, the rein-deer, which dwells with man, and is a most useful servant of all work, and means of subsistence to him in climates where no other vegetable feeder can exist.

In the north, too, we find the deer of much larger stature than they are in warmer climates; and this is an additional confirmation of the necessity of furnishing the vegetable feeders of the extreme latitudes with some permanent energy beyond that which is required for the mere purpose of feeding, in order that they may continue their race, keep their post, and preserve the balance of nature in those climates where life has, for full four months of the year, to maintain itself against cold sufficiently intense for freezing mercury, while for two or three months in the opposite part of the year, every living thing is scorched by the ardour of a never-setting sun. It is in these grand adaptations that we see most strikingly the oneness of the system of creation, and catch glimpses of that splendid science, that incomprehensible wisdom of design, which runs through the whole, and which preaches more eloquently than the tongues of men or of angels.

Those who have not thought much upon such subjects may be apt to imagine that, as the horns of deer

are in highest perfection at the time when the energies of the animals are required for the performance of those functions, at the close of which the horns drop off, the energy is most occupied in the horn, at the very same time that it is required for the other purpose; and that, therefore, the horn is a source of division and weakening of the energy, and not a concentration and strengthening of it. But when they call to mind that it is during the growth, and not when full grown, that the horn exhausts the energy of the animal, that the growth is most rapid in the early stage, and that the growth ceases when the skin comes off and the bony part of the horn is left bare, it will at once be seen that there is no ground whatever for such a supposition, but quite the reverse. There is something very analogous to this in the flowering of plants, which will probably suggest itself to the reader, but the introduction of it here would be out of place.

With the exception of these climatal adaptations, the deer form a more distinct and perfect genus than any of the other ruminantia, or, indeed, than almost of any group of any other order whatever; and, therefore, though there have been some attempts to separate them into sub-genera, the distinctions upon which these have been founded are more fanciful than real. The species are tolerably distinct, even when they are found in the same countries; but even there each species affects a different pasture; and, therefore, though we describe them according to their different appearances, the real distinction is one of locality.

Here we are somewhat unexpectedly brought back to the physiological doctrine which we are attempting, for the first time we believe that it has been attempted, to explain—or, perhaps, to speak more becomingly, which we are seeking to bring to the notice of those who are capable of explaining it; for the explanation points much farther than even most physiologists are in the habit of looking, or even dreaming (for they dream homewards, and not on the long view); and we very much suspect that, if clearly worked out with constant adherence to the facts, and the whole volume of nature open to the investigator, it would be found as wide as the entire working creation, both animal and vegetable.

We may just notice that among birds, the gallinaceous ones, and others which, though not exclusively vegetable feeders, as indeed no birds are, yet never fight with what they eat, are the ones in which the male undergoes the greatest change of plumage as the pairing season comes on.

There is yet another point: among those birds which change their plumage toward the pairing time, the species in which the males are polygamous have the greatest and the richest change of feather in them. So also in the deer there is one species which is not polygamous, and in this species there is less development of horns, and also less excitement in the season of heat than there is in those where the males are polygamous.

The chief ground of specific distinction in the genus *Cervus* is the form and production of the horns; and this we might be prepared to expect from what has been already stated, or if we are to take the forms of the horns as an observed fact (which of course it is), it is a further argument in favour of what has been stated.

Deer have been in all ages of the world among the most interesting of its wild inhabitants. There is

majesty in their appearance, there is fleetness in their march; their flesh is more esteemed than that of any other animals; and when they are “in pride of grease” as it is called, they are in higher condition than any other animals ever are in a state of nature, or can be brought to by all the arts of the most skillful cultivator. Beeves and muttons may be fatted *ad nauseam*; but after a moderate point, as the fat accumulates the flavour goes; and a haunch of venison from the hill is, in point both of juiciness and of flavour, superior to all the beef or mutton that ever was fatted. As a proof of its superior wholesomeness we may add, that, even in the hottest weather, venison is hardly ripe in double the time in which beef or mutton would be putrid. The common-blue bottle fly tells tales in this respect: that insect is attracted by the scent of incipient putridity, as blue bottles may be observed most plentiful about those butchers’-shops where both the shop and the meat are in the worst condition.

The fleetness and watchfulness of deer, the boldness with which the males turn on their pursuers when pressed to extremities, and their value when caught, have made them at all times the most favourite game with the hunter, both for killing with missiles in the woods, and for running down by dogs in the open places. Indeed, it is highly probable that it was the deer which taught mankind the use of the bow in many countries in the earlier periods of their history, though Canning in his exquisite satire, “The Progress of Cruelty,” bestows the honour of having suggested this invention upon the pig—in his eager desire to eat which, the wild man applied the barked string to the bended branch, laid the pointed reed across, drew with all his might, let slip, and

Twang sounds the string, the hissing arrow flies,  
And darkness seals the gentle porker’s eyes.

While great part of England was covered by extensive forests of timber, the shooting of deer formed, in the season, the occupation of kings, and feudal lords and their vassals, and, except in trying their weapons upon each other, it was almost their only amusement. It also formed a stock theme with the romancers and poets of the time; and, though it is partly true and partly fabulous, there are few of the remains of the lore of the middle ages which has had more readers and admirers than the story of Robin Hood and his band in Sherwood Forest. Nor in the more open parts of the country was the wholesale slaughter of the deer by driving in one way or other a less celebrated employment; and when “the stout Earl of Northumberland” wished to bring the feud with the Douglas to an issue, he had recourse to a deer-stealing incursion upon the grounds of the latter:—

To drive the deer with hound and horn,  
Earl Percy took his way;  
The child may rue that is unborn,  
The hunting of that day—

as is said and sung in the very beautiful and truly national ballad of Chevy Chase. Innumerable other instances might be cited to show the importance which our forefathers attached to these animals; and it is probable, nay it is certain, that to the fondness both of men of rank and of men of no rank for deer, we are indebted for the brightest ornament not only of English literature, but of the literature of all nations.—William Spakspere was a deer stealer, and as such was driven from his native county to seek shelter in the British metropolis, and make his way there the

best way he could; and, from the miserable doggerel in which he vented his indignation against those who had punished him, there is every reason to conclude that if Shakspeare had remained in the country, he never would have been the author of one readable line. Therefore, the deer may be said to have given us more than man by force of armies, or by strength of reasoning, could have given us—it has given us Shakspeare.

Deer belong more to wild than to cultivated nature; and more to the rude and early stages of countries than to the more polished and advanced periods. They are also inhabitants of northern climates rather than of central ones; and in the extreme south are unknown as native animals. They are found throughout the continent of Europe and Asia, and in the more proximate Asiatic isles; but there is not a vestige of them or of their remains in any of the islands of the great South Sea, in Australia, or in Africa, as native animals. They are found, indeed, in the north of Africa, on the slopes of the mountains of Atlas, but there is not the least doubt that though now naturalised there, they were originally imported: there is not a vestige of them to the south or the east of the desert of Sahara, though all that part of Africa swarms with antelopes; and the southmost of the Asiatic isles in which they are met with is Timor, where the species is very small, and by no means abundant.

In America, their grand head-quarters is the north, though they continue downwards along the mountain slopes, and in the extensive forests, a good way into South America; but although there are several species in that part of the western continent, it does not appear that there is even there any one which can, with propriety, be called an Antarctic or southern deer. Thus we may regard them as being properly animals not merely of the northern hemisphere, but of the extreme north, for the species which are found there are of far greater size than those farther to the south, and also more abundant in numbers.

Although some of the species are comparatively tame, and one in particular, the rein-deer of the north of Europe, is in a state of complete domestication, yet, as a genus, they cannot be ranked among domestic animals, and they fade away before the progress of cultivation. In the state of nature, they, generally speaking, frequent grounds which are rather rich, and most of them either the woods or their margins. Some of them are fond of marshes, and the banks of streams, and even take to the water at a certain season of the year, and all of them can swim. In locality and food the species differ a good deal, so that we shall mention these particulars along with our notice of the species themselves.

The following are the generic characters: eight incisive teeth in the lower jaw, but none in the upper; no canine teeth in most of the species, though some have them in the upper jaw; six grinders above and below on each side; head long, terminated by a muzzle, and with the upper lip more or less elongated and prehensile in the different species; the ears very large; the eyes bright and clear, with the pupil elongated; sub-orbital sinuses, or slits under the eyes, in the greater number; tongue soft; no gall-bladder; the female with four mammæ in the groin.

As, in the former part of this article, our physiological remarks on the use of the horns in the economy of the animal took our attention from the description of them, and as that is a sort of technical matter,

which it is sometimes reckoned unclassical not to know, we shall mention a few of the particulars. The ring of irregular protuberances which surround the horn at its base is called the *burr*; the main stem of the horn is called the *beam*; the divisions on the upper part of the beam are called *branches*, or *snags*; and the branches next the brows, of which there is one, two, or three, according to the species, and there are occasionally, but rarely, some irregularities in the same species, are called *antlers*; and the first of these is called the *brow-antler*, and the second the *bezantler*. The rudimental horns, which appear the first year, but they do not make their appearance till the year is out, that is, till the summer after they are dropped, are called *prickets*, and the little protuberances on them, which mark the rudimental antlers and branches, are called *dags*, which name is also sometimes given to the prickets. In some of the species, and it is most remarkable in the southern ones, the beams and branches are all slender, and nearly round in their sections; but in other species, and most conspicuously in the most northern ones, the beams, and in some also the antlers, have flattened extremities, which are called *palms*; and when the beam is much palmated, the terminating branches are usually short snags. In the stag, when full grown, snags appear on the front edge of the upper part of the beam, or the forward branch, in which case the animal is called a "fore-hand stag."

During the time of its growth the horn is sentient, and bleeds when wounded, and a wound upon it will sometimes occasion the production of an additional snag. The following is an account of the progress of the horn:—At first a slight protuberance appears covered by the skin, where a great number of vessels are spread, for a considerable degree of heat is perceptible under it. Soon the protuberance rises, and in some species branches off into ramifications. After a certain period, the development is arrested, the skin, which had continued to stretch and extend over the whole production, loses its heat, dies, becomes dry, and finishes by tearing off in rags. At length the horn itself becomes detached, and falls; a slight hemorrhage follows from the skin, or the part of the frontal which sustained it. In the course of twenty-four hours, in healthy deer, the vessels which emitted the blood are closed, a thin pellicle covers the wound, and immediately the reproduction of a new horn becomes apparent; the extremity of the vessels swells, a burr expands around the base where the late horn stood, resembling those on the bark of trees when they have received wounds which begin to cicatrize; the burr widens, while the vessels which proceed from the bone deposit osseous matter. Hitherto the development of the horn has been uniform, the vessels have extended in a certain direction, always the same in each species; but when they have arrived at a certain point, they separate, some continuing as before, while others turn into new, but always invariable directions, if no accident impedes them. The horns of each year come up with a branch or snag more than in the preceding year, so that they serve for a sort of register of the age of the animal. No male deer is said to be "of the first head," till there are five snags or branches; and after that he is counted, and ranks in hunters' honours by the number. When he is "a stag of ten," he is accounted a noble animal.

In giving an account of the various species of deer

we shall take them as nearly as possible in the order of their locality from the north southward, subdividing them at the same time into a sort of three groups, which, however, are also local groups—those which are found both in the eastern continent and in America—those which are found in the eastern continent only—and those which are found in America only.

#### I. DEER COMMON TO BOTH CONTINENTS.

**REIN-DEER** (*Cervus tarandus*). This species is the *Reen* of the Laplanders, and the *Carabou* of the natives of the extreme north of America. There have been doubts raised as to its identity in the two continents, but these doubts do not appear to be well founded, as in both countries the manners and general appearance of the animal are the same. It is the most polar of the whole genus, subsisting where no other ruminant animal could subsist, and upon food which could support scarcely any other animal; and it is as gentle in its manners as it is endearing, being all in all to the Laplanders, where no other animal can be of use to them, either for labour, or, in as far as ruminant animals are concerned, for food. In the more northerly parts of Europe it is alone, but in the north of America it blends with some of the other species. This is not, however, owing to any difference in the animal, but to the difference of the countries. The winter in Lapland is much milder than in the north of America, even in latitudes much farther to the south; and the Lapland summer is not so burning as that of America; therefore there is a difference in the seasonal shifting of the quarters of the animal. In Lapland it goes to the mountain in summer, and descends to the valleys in winter; and as the sea is not frozen even at North Cape, the cold of the Lapland winter is not excessively intense. At the north of America, on the other hand, the sea is completely frozen over, the cold is extreme, and, from the depth of the snow, food for the rein-deer there is altogether inaccessible. In consequence of this, it migrates more to the south, or farther in latitude than in Europe.

Rein-deer.

Rein-deer vary considerably in size; and we have this proof, that though they are docile, and breed in a domestic state, that state is not quite congenial to them; that they are always of more diminutive size when domesticated than when wild, even though they should happen to be better fed. In the wild state, the full-grown male is equal in size to the full-

grown stag, or perhaps even larger, but its legs are more clumsy, its body is more squat, and, altogether, it is a much less graceful, as well as a much less courageous animal, than the stag. In the general shape of its body, it bears some slight resemblance to a calf. The neck is very short, the head carried in a line with the back, and, altogether, the aspect of the animal is heavy. Its body is covered with two sorts of hair, one having considerable resemblance to the hair of the rest of the genus, and, like that, having a narrow neck at the insertion of each hair into the skin. This form of the individual hairs is, so far as we are aware, common to the whole genus, and might, on that account, be made a character, as it is not met with in almost any other animal. The hair has something the form of an old-fashioned lance, which was thickened toward the handle, to give it stiffness, then had a narrow place for the hand to grasp, and beyond that another thick portion for fixing, or setting on the rest. In the hair of the deer the latter portion is inserted in the skin, a small part close to the skin is a mere filament, and then the remaining, or principal part of the hair, is thick, and tapers to a point. In consequence of this formation, the hair easily separates; but it lies flat, and does not stand on end when the animal is excited, as hairs do which are thick at the roots. This answers to not unimportant purposes. In the first place, when the animal is exposed to rain, the hairs fall flat over each other, and throw off the water like a roof; and in the second place, these flexible-rooted hairs give way to the air much better than stiffly-rooted ones would do, and, in consequence, the animal is less fatigued while making its escape from its enemies. Besides this hair, which is common to all the genus, the reindeer has short woolly hair among the roots, as is the case with most animals of very cold climates. In winter, there is a third kind of hair, which is long, only thinly scattered over the upper part of the body chiefly, and of a whitish colour.

The colour of the rein-deer hardly admits of any definite description, for there are great varieties even in the wild state, and, as we might expect, the colours of the domesticated ones vary almost as much as those of cattle. There is what is understood to be a sort of typical marking, namely, brownish, with white, round the mouth and the horns, and also on the shoulders, extending in a bar to the flanks and rump, and under the tail, and white also round the hoofs. The belly, and insides of the limbs, are also generally white; but some of the wild ones, and many of the tame, are white all over. The fawns are generally brown on the upper part, reddish on the under, and dappled with white spots.

The horns of the male are generally much produced and broadly palmated, being sometimes as much as four feet long; those of the females are much smaller, and have the palms narrower. No fixed account or representation can be given of the form of the fawns, but in general the beams are thrown back from the forehead, and then bent forward with a considerable sweep. On their front sides they bear two branches, which are sometimes simple antlers, and at other times palmated or snagged. The remaining snags are on the back of the curves.

The males drop, or, as it is called, *mew* their horns about the month of November; and the females, when not in fawn, drop theirs at the same time; but,

as already mentioned, the females which are in fawn do not drop their horns till they have brought forth. If the male is mutilated, it has the effect of making the horns remain on for one whole year; but after this they are shed at the same season as those of the entire animals; and, as is the case with cattle, they increase rather than diminish after the operation. This might be expected, inasmuch as the energy which is divided in the entire animal goes wholly to the formation of horns in the other. The rutting season is in October, at which time the males growl something in the same manner as fallow-deer. They have an apparatus in the throat, which we believe has not been detected in any other of the genus, namely, a membranous sac, between the thyroid cartilage and the *os hyoides*, opening by a slit into the larynx, and capable of being inflated with air, somewhat similar to that in the howling monkeys; but what effect this may have on the sounds which they utter has not been ascertained.

The fawns are usually dropped in May, they are one or two, but rarely three; when dropped they have rudimental horns, and these become snags an inch in height in the course of two weeks, so that in this respect they differ from all the deer of warmer climates.

They are excellent swimmers, and ride so lightly in the water, that half their backs are above the surface; their broad feet strike with great force, and impel them so fast in the strongest currents and across the broadest rivers, that a boat well-manned can scarcely keep pace with them. When defending themselves, they strike downwards with the horns, but do not gore; they kick with violence, and repel the wolf with success; but their most dangerous enemy is the glutton, who is reported to drop down upon them from the branch of some tree while they are off their guard, and both that animal and the bear are apt to watch in trees, and drop down upon them as they pass. The feet of the rein-deer produce a cracking noise when they run, by the hoofs striking against each other.

Rein-deer are remarkably well provided with the means of finding their way. The nictitating membranes of their eyes move with nearly the same facility as those of birds; so that they can proceed directly against the heavy falls of snow which are so common in that country in the early part of the winter. Their sense of smelling is equally acute; and by that alone they can not only find their way in the darkest nights, but conduct their master with perfect safety in his sledge, at times and through places where human sagacity would be utterly at fault.

There is no animal, indeed, so serviceable to man in any country as the rein-deer is to the Laplander; and if he were deprived of it he could not by possibility exist. With its assistance, however, his condition is more comfortable than one would readily suppose, and there is nothing which he could substitute in the place of this most useful animal. It feeds upon those plants which form almost the extreme of vegetation,—the buds and twigs of the small arctic shrubs, and the lichens which grow abundantly where nothing else will grow; and thus he does not require to sow grasses, prepare meadows, or cultivate any sort of vegetable, but may be said to obtain the labour of this excellent servant for nothing. All that he has to do is to protect his little herd from the bear and the glutton, and guide them to their changes of pas-

ture as the different seasons of the year require. In the wild state they are gregarious, and when domesticated they are perfectly social, very much attached to each other, and obedient to the orders of the herdsman; an elder of the herd generally takes the lead, and the rest follow him with a most willing obedience. The herdsman teaches this leader to obey his whistle, and the rest will follow after, at almost any signal, such as a stamp of the foot, or even a look. They draw the sledge over the snow with great rapidity, and apparently with less fatigue than any other animals of draught. No doubt the hard and smooth surface of the snow is a sort of railway, or at least bears some resemblance to it; but still it is no small feat for two deer to draw a man in a sledge over "three skies" of the Lapland mountains in twenty-hours. A "sky" is a mode of estimating distance understood in most mountainous countries; it was once very general in the islands of Scotland, and is still used in those places where there are no roads. It means a new horizon, which the traveller obtains every time that he comes upon the top of a new hill. These skies are, of course, of very different lengths; but from the character of the country the average length of three taken together may be reckoned at not less than one hundred miles; and we are not aware of any other means by which a man could be drawn the same distance over snow during twenty-four hours of a sunless night.

But this is not the only advantage which the Laplander derives from the rein-deer: the flesh of the animal is the most substantial part of his food, and its milk serves him in various ways. It is used recent; it is coagulated into cheese, the whey is used for drink; and we believe in some instances fermented, and distilled into a liquor something analogous to that which the Tartars make from the milk of the mare. The skin of the rein-deer, which is warm and strong and pliant, serves for a clothing, for blankets, for covering the sledge, and for almost every purpose for which we apply cloth or leather. The tendons, which are very tough, furnish thread; the horns are manufactured into a variety of domestic utensils; and even the intestines of the animal have their domestic uses, while the tongues, which are considered luxuries in most countries, give even the poor Laplander an export trade, and make even him a citizen of the world.

There is no country in Europe so much infested with the plague of flies as Lapland, especially in the swampy and shady places, where the gnats are almost as tormenting as the mosquitoes in tropical countries; to escape from these the Laplander and his herd take to the open hill in the summer; but even there the animal is not secure from insect annoyance. Even in the most elevated and airy of its mountain pastures, the rein-deer gad-fly (*Estris tarandus*, Linnaeus,) finds out the herd, and the hum of a single insect is sufficient to throw the whole into a state of the greatest agitation. The object of the fly is to deposit its eggs under the skin of the animal, which it generally succeeds in doing; and it is said to be when the rein-deer are about two years old that they are most annoyed by this insect.

Estimated by this, his most valuable possession, the Laplander is often a man of no small wealth, for his herd sometimes amounts to as many as a thousand; and as two is the average production of each, and the number of females far exceeds that of males, this herd furnishes him with an abundant supply of all the

necessaries of life ; and from the different numbers which different individuals possess, and some being without any, there are grandesees and paupers in the wastes of Lapland, as well as in the most fertile and thickly populated countries in the world.

In Lapland properly so called, and in all the country northward to the Gulf of Bothnia, we believe that there are now few rein-deer in a wild state, if, indeed, there are any ; neither are they met with in the southern or lowland parts of Sweden ; but in the central province of that country they are still to be found in considerable numbers. It does not appear that the species ever existed in Europe to the south of the Baltic, though as we proceed eastward and the cold extends farther to the south, we find rein-deer farther to the south also. They range eastward over the whole continent to Asia, and northward to all the isles of the Frozen Ocean, whose icy plains afford a ready passage ; and from the structure of their feet they are well adapted for making rapid way upon the ice ; and, indeed, it forms a better passage than the land, as it is more level, and always covered with a coating of snow. They are met with in Spitzbergen, which is near the eighteenth parallel of latitude, where man, notwithstanding his flexibility to climate and his mental resources, is unable to endure the winter. On their migrations rein-deer no doubt frequently meet with their polar neighbour the white bear ; but we believe he is unable to come up with him on the ice.

The circumstance of no trace even of the bones of the rein-deer being found in a fossil state in central or southern Europe, decides that in all ages of the world, this has been strictly a polar animal ; and the fact of its seeking the verge of the Frozen Ocean, and journeying upon the ice, proof against the very extreme of the winter's cold, readily accounts for the fact of its being found both in Europe and in America. The continents approach one another very closely on the side of Siberia ; and even in the summer months the ice is so little way to the northward of Behring's Strait, that even then it would be no very arduous march for a reindeer to pass from Asia to America, or the reverse. It is probable, however, that the intercourse, if it is still kept up, takes place during the winter ; because at that season the animals descend, while in summer they seek the elevated spots.

These circumstances and the facts which we have mentioned of the variations of colour to which rein-deer are liable, clearly establish that though there may be variations in the average colour of the rein-deer of Europe, and the *Carabou*, as it is called in America, that they are the same identical species. The horns are said to differ at least in some of those which have been considered as varieties in America ; but these appendages differ so much even in the same herd, and sometimes in the same animal, for the one horn is often very differently shaped from the other, that no species or variety can be founded upon any variation of these. Whether the rein-deer passes along the polar ice from Spitzbergen to Greenland, we have no means of ascertaining. It is possible, though not very likely, that with the exception of this one break of its range, this most polar of all the ruminantia has unbroken command of the entire circuit of the earth ; and on this, its peculiar locality, as well as for its usefulness to man, in the land of his greatest necessities, the rein-deer is one of the most interesting of animals.

Before we pass to another species it may not be amiss to notice merely for the purpose of showing how unlikely it is to be true, that some naturalists have described the fossil horns found at Etampe in France, to which horns an animal has with most gratuitous ingenuity been added, under the name of *Cervus Guetardi*, as belonging to the reindeer ; but from what we have said of the variable nature of the horns, as well as from what we may call the demonstration by the late Cuvier, who was at once the most learned and the most cautious judge in such matters, there seems decidedly to be no truth whatever in the assertion.

**THE ELK (*Cervus alces*).** This is the next in order in geographical position, its locality lying immediately to the southward of that of the reindeer, and the two bivoculating with each other on their confines in the eastern continent, and still more in the western. The elk, which was once pretty numerous in central Europe, is now rare in that quarter of the world, though it is still not unknown. In America it is much more abundant, and inhabits further to the south, its head-quarters being the vicinity of the great lakes, and the forests on both sides of the St. Lawrence ; the whole of Canada in fact with New Brunswick, and also westward, at least as far as the Rocky Mountains, which come down upon the northern ocean, or rather the Polar Sea to the westward of the debouchure of Mackenzie's River, in about 185° west longitude. It is not mentioned that the animal has occurred to the westward of those mountains, and, though not impossible, it is not by any means so probable as that the reindeer should be there ; for besides the elk having a less polarly situated locality, its habits are different. The reindeer is adapted to the dry lichen-clad hill in the summer, and to the snow in the winter ; while in summer the elk is more in the marsh, and sometimes actually in the water feeding on the submerged grass, and ever and anon blowing somewhat like a whale, and in winter it is more in the forest.

Still there is no reason to suppose that there is any specific difference between the elk, or moose deer as it is called in America, and the elk of the eastern continent. No doubt black elks and reddish elks, and sometimes also white elks, have been described ; but the elk is subject to very considerable changes of colour with age, the very old ones being apt to turn almost black ; while the young ones are chestnut coloured, and there is little doubt that the white individuals are albinos.

We cannot resist quoting the following very accurate and highly graphic description of the elk, from the pen of Colonel Hamilton Smith, whose monograph on the ruminantia forms the greater part of the fourth volume of the English translation of Cuvier's Animal Kingdom, published in the name of Griffith, which monograph most justly called forth the highest eulogium from the illustrious author of the original work. "This animal is the largest of this genus, being higher at the shoulders than the horse ; its horns weigh sometimes near fifty pounds ; accordingly, to bear this heavy weight, its neck is short and strong, taking away much of the elegance of proportion so generally predominant in the deer ; but when it is asserted that the elk wants beauty or majesty, the opinion can be entertained by those only who have seen the female, the young, or the mere stuffed specimens ; for we who have had the opportunity of view-

ing the animal in all the glory of his full-grown horns, amid the scenery of his own wilderness, no animal could appear more majestic or more imposing. It is, however, the aggregate of his appearance which produces this effect; for when the proportions of its structure are considered in detail, they certainly will seem destitute of that harmony of parts which in the imagination produces the feeling of beauty. The head, measuring above two feet in length, is narrow and clumsily shaped by the swelling upon the upper part of the nose and nostrils; the eye is proportionally small and sunk; the ears long, hairy, and asinine; the neck and withers are surmounted by a heavy mane, and the throat furnished with long coarse hair, and in younger specimens encumbered with a pendulous gland; these give altogether an uncouth character to this part of the animal. Its body, however, is round, compact, and short; the tail not more than four inches long, and the legs, though very long, are remarkably clean and firm; this length of limbs and the overhanging lips have caused the ancients to fancy that it grazed walking backwards. The hair of the animal is coarse and angular, breaking if bent."

The elk is an inhabitant of northern latitudes; in Europe between the fifty-third and sixty-fifth degrees, making a part of Prussia, Poland, Sweden, Norway, Finland, Lapland, and Russia. In Asia it is found farther south, from thirty-five to beyond the fiftieth, spreading over Tartary, and abounding in Japan, if indeed the denomination of elk is not misstated for that of a *rusa*, or an undescribed species. In America it resides between the forty-fourth and fifty-third degrees, round the great lakes, and over the whole of Canada and New Brunswick.

Its movements are rather heavy, and the shoulders being higher than the croup it does not gallop, but shuffles or ambles along, its joints cracking at every step with a sound heard to some distance. Increasing its speed, the hind feet straddle to avoid treading on its fore-heels, tossing the head and shoulders like a horse about to break from a trot to a gallop. It does not leap, but steps without effort over a fallen tree, a gate or a split fence. During its progress it holds the nose up, so as to lay the horns horizontally back. This attitude prevents it seeing the ground distinctly; and as the weight is carried very high upon his elevated legs it is said sometimes to trip by treading on its fore-heels or otherwise, and occasionally to give itself a heavy fall. It is probably owing to this occurrence that the elk was believed by the ancients and the vulgar to have frequent attacks of epilepsy, and to be obliged to smell its hoof before it could recover; hence the Teutonic name of *eleud* (miserable), and the reputation especially of the fore hoofs as a specific against the disease.

During the winter months the elk resides chiefly in hilly woods, in snowy weather seeking the covers, and in clear the open spaces. In summer it frequents swamps on the borders of lakes, often going deep into the water to escape the sting of gnats, &c., and to feed without stooping. Its usual food in winter consists of the buds and bark of button-wood, spruce, and juniper pines, birch and maple, and under the snow it seeks stink wood (*Anagyris fetida*) and mosses, but this is always with difficulty, for then it is obliged to spread the fore legs, or even it is said to kneel. The branches of trees it turns down with the horns very dexterously; but to get at the ground we have been assured by Huron and the Canadian hunters,

when the snow has fallen only a foot or two in depth, that the herd, led by an old male, shovel it back, and throw it over their heads, the snow falling on either side, as it slides from the inclined planes of the back of their horns; meantime the fore feet of all are equally engaged in striking it from under them.

During a part of the year the herd consists of an old female, two adult females, two young females, and two young males; but during the snowy periods, at least in America, one or more adult males are certainly among them, very old males alone keeping aloof until the rutting season, unless the winter be very severe. Several of these families keep near each other, and in very cold weather they seek cover together, and remain closely pressed against each other, or trot in a circle till they have beaten the snow down. When the rutting period commences, which is about the beginning of September, the old males seek the females, and expel the young, who are obliged to keep aloof while the animals remain in heat. At this time they will swim rivers in pursuit of the females, or after them to remain concealed in some of the Lake Islands. The males are then very pugnacious; they bellow often and sink in flesh. The gravid females bring forth about the middle of May, at first one, but ordinarily two calves, of a brown red colour. These are so simple and void of fear that in the first months they are easily taken, and if in the water, where they willingly go to avoid the flies, they will suffer persons in a canoe to come up to them and take them by the head without appearing in the least frightened.

The dags, prickets, or incipient antlers are the first year not more than an inch in length; the second they rise to a foot; the third they are forked, and the fourth they assume six snags and are somewhat flattened; the fifth year the blade is still small, but their expansion from that time forward is uniform, though it does not appear that the number of snags ever exceed twenty-eight. In a very large specimen which we saw shot, there were twenty-two, the length from the head to the tip twenty-seven inches, and from tip to tip across the horns three feet six; the two lower snags on each side separated by a deep indentation: the weight about thirty-three pounds. Old elks shed their horns in January and February, and, if lean from a severe winter, in March; the younger later, till the month of May. They are again completely restored in the former by the end of June, and in the latter in August.

"An elk killed in Sweden is said to have weighed 1200 pounds, but this must have been a very extraordinary animal; their height is about six feet. A white specimen from Swedish Lapland, in the Munich Museum, five years old, is six Rhineland feet at the shoulder. A female figured by Mr. Heriot was seventeen hands high; the large male above alluded to was scarce four inches more, or about six feet, but he was very deep at the shoulders. Another, whose antlers were still more deeply indented at the base, that is with the parts corresponding to the brow and bezantlers of the stag, separated from the main blade by a deep intersection, was not more than seventeen hands and a half high. His head, from the nose to between the ears, two feet three inches; distance between the eyes eight inches; length of the ears nine inches and a half; the lower branches or snags were bifurcated and thirteen inches long, and their united amount was seventeen, with the rudiment of

an eighteenth. The hunters named him a black moose, and from the greater length of head in proportion to his height, and the particular form of the horns, insisted that this was a different species from the brown. There is however no character sufficiently distinctive to claim our assent to this assertion, for it is known that considerable variation in the horns occurs from various causes, although it must be admitted that the almost complete separation of the lower parts into the form of branches is a very prominent character in most if not all the American specimens, while a similar formation is rare in those of Europe, but the colours of the hair differ with the season; and if this specimen belong to a different species, both would be of that species, the result proving only that the European is not of the same. The two here mentioned were dark, almost black, with grey hairs intermixed, but that with the largest horns had the greatest intermixture of grey; they were killed on the borders of the Saquenai, in Lower Canada, where both they and a herd of buffaloes were considered as strangers. The darkest was shot in September, and the grey in November, which may account for the difference of colour.

"During the time that their horns are sprouting, the animals remain most in willow covers, returning to the evergreen woods when they are restored; their period of life does not exceed twenty years.

"They are hunted in North America chiefly during the early part of winter, and towards the spring. While the snows are not deep they are not easily attacked; but when they begin to harden, and the hunters run on snow-shoes, they endeavour to turn the game towards ravines, or where it is drifted deep. The Huron hunters have assured us that when this is effected he is sure to be soon entangled, and to flounder in it; but that they must be on their guard, and run instantly upon the deep snow to fire at him as he turns, because he will endeavour to double on his own track, and charge all that are then in his way. When first discovered, he is often found sitting on his hams like a dog, voiding his urine before he rises to escape. Against the bear and the wolf, he stands at bay with his horns, acting offensively only with his fore or hind feet; his kick is very powerful and quick; it is said that a small tree is splintered by it.

"The Indians are great admirers of the flesh, to us it appeared superior to the stag's; but under the circumstances which admit of this kind of banquet, it may be doubted whether a similar judgment would be passed in the comforts of a home; the nose and the tongue are admitted to be the best parts. Mr. Pennant states that they were once used to draw sledges in Sweden, but that it afforded to malefactors the facility of escaping, and that therefore the use of them was prohibited. The hide furnishes excellent leather and buff skins for belts."

It has sometimes been alleged, that the very large deer's horns which are found abundantly in the bogs of Ireland, and sometimes, though more rarely, in similar formations in Britain, are horns of the elk; and it has thence been inferred that at one time the elk was very plentifully found in the former island, and by no means rare in the latter. But there is no reason to conclude very dogmatically from the horns themselves, because, as we have already said, they are subject to great variations even in the same country and at the same time; and therefore we can

satisfactorily draw no conclusion from them as to what may have been the animal whose remains are so common in these deposits. But we have conclusive evidence that the animal to which those horns belong, and which must have been at least as large as a cart-horse of the present day, was a stag and not an elk; because the skeleton has been found, and the relative proportions of the bones are exactly those of the stag; but whether of the stag which is still found in the old continent, and which has degenerated in consequence of change of climate in the lapse of centuries, or of some more gigantic variety which is now extinct, we have no means of ascertaining; and therefore it would be idle to offer any conjectures on the subject.

That Ireland and many parts of Scotland, more especially the western islands, and the isles, have undergone a very remarkable climatal change is certain. They are now almost entirely denuded of timber, except a few wretched copses of underwood, and a few artificial plantations; and in both, black or red peat bog has come in the stead of what once were forests of the most gigantic trees. When those forests were in their prime—and glorious forests they then must have been, for the writer of this article has traced the remains of a single tree full 150 feet in length—when they were thus in their prime it is natural to suppose that they were inhabited by deer worthy of them; and that from whatever cause, or by whatever catastrophe, the goodly forest and its gallant inhabitants have faded away. It is generally said that the invaders of Ireland wantonly consumed the forests with axe and fire-brand, and as wantonly exterminated the deer, but this wants confirmation; and besides it does not come within the pale of natural history, and would not explain the phenomena in question although it did. When we look at the grand features of the natural world, we may put aside the small results of man's working; for there is a maturity and a decay in certain states of countries which man cannot greatly, or perhaps even sensibly, either accelerate or retard. Besides, we know of no such catastrophe in the parts of Scotland to which we have alluded; and there we find a few lingering remnants of the forest which tell us of its former existence, and that it has yielded to the powers of nature, and not to the hand of man. In many places there are the roots of yews with a small circle of the external or last formed wood still undecayed, and sometimes with green foliage the size of a feather upon some portion of the ample circumference. These were in the rich bottoms no doubt, but at all events they are now in the wilderness; and some of them measure fifteen or even eighteen feet across, so that they must have been giants in their day. Besides, in situations which are too bleak, and beaten by the winds and rain of the Atlantic, for suffering fungi to sprout and moss to accumulate for (such are the beginnings of a peat bog), there are still immense trunks lying bleaching, white and sapless, and unfit for affording nourishment to even the smallest fungus which can grow upon a fallen tree. This is not, however, the place to enter upon such subjects, though it is difficult to discuss the natural history of deer without at the same time thinking of the progressive history of forests, and being carried back in imagination to times when our country had far more of a natural majesty in it than it has at present, notwithstanding its arts and its wealth; and though our habits are such that we

would not willingly part with these, yet it is refreshing sometimes to glance back in imagination to those glories of the land which are gone for ever, until some convulsion of the globe shall depress our islands to "the oozy bottom of the deep," and let them rest there during the night and sleep of lands until another convulsion of nature shall again upheave them, like a giant refreshed, and fitted anew for giant plants and gigantic animals.

## II. DEER OF THE EASTERN CONTINENT.

The two species which we have enumerated, namely, the reindeer and the elk, are the only two which can be considered fully established as inhabiting both the eastern continent and the western; and though the elk inhabits more southerly and in richer pastures than the reindeer, yet it is sufficiently far in the north for allowing the supposition that it may have passed from continent to continent upon the ice. Those which remain to be considered are the deer of temperate and of warm countries, which inhabit too far to the south for interchanging between the continents; and though there are exceptions as regards particular places, which are explainable by the different characters of those places, yet we may in general say that the size of the animals, and especially the development of the horns, diminish as we approach the southern limit.

In most countries, however, which are adapted to the race, and from which that race has not been exterminated by natural or artificial means, we may say that there are in general three species of deer, one affecting more the forests, another the open savannahs or rich plains, and the third the more elevated and airy wastes. We may thus style them according to their pastures—forest deer, field deer, and hill deer. We have types of all the three in this country, though it is possible that the field deer, the one with which we are most familiar, but which partakes not of the majesty of him of the forest, or of the airy beauty of the mountaineer, may be an importation. We shall first notice these three in their order, and then briefly mention the foreign varieties.

**THE STAG** (*Cervus elaphus*). This is the deer par excellence in all works on "the noble art of venerie," and in all allusions to the bold foresters of merry England. It is the red deer, and the male is called a hart, and the female a hind.

The characters are, the horns round in their section, furnished with three antlers on each beam, turned to the front, and curved a little upwards; then the top of the beam terminates in a number of snags, all at nearly the same elevation, and increasing in number with the age of the animal. In summer the general colour is yellowish brown, with a black bar across the shoulders, and a row of pale yellow spots on each side. In winter the colour changes to a uniform reddish brown; but the hinder part of the rump, the tail, and a small portion of the feet above the hoofs (which we term the fesses), are always of a pale yellow.—Both sexes have canine teeth, which are rather long, and bent in the male, but the female has no horns.—The young fawns are of a rich yellowish brown, dappled with white spots; and it is from their ground colour that dyers give the name of fawn to a peculiar shade of colour, intermediate between brown and yellow. The colour deepens much with age; so that in winter the old stags are nearly black; but they retain the mark on the crupper and fesses.

The stag is by much the largest of European deer,

and the probability is, that the large horns above alluded to have belonged to the very species which is still met with in some parts of our own country, and more abundantly on the continent of Europe, where forests are far more extensive, and have been less disturbed. The rutting time of the stag is in September, the young one being driven off by the mothers in August, and during this season the males are in such

Stag or Red Deer

a state of excitement, that it is not only highly dangerous to approach them, but they sometimes ill-treat and even kill the females. The hind goes a few days more than eight months with young, and drops her single fawn, for she has rarely two, in the month of May. It used to be fabled, that the stag was remarkable for length of life; but it does not appear that it lasts longer than about twenty years. It is found less or more in all places of Europe, where there is cover adapted for it, except in the extreme north and in very hot places near the sea. It is also met with in western Asia, in some of the mountainous islands of the Mediterranean, and on the slopes of the mountains of Atlas in northern Africa, where it appears to have been imported, probably by the Romans. But it has degenerated in that part of the world: it is smaller in size, more brown in the colour, and the horns terminate in forks, instead of the numerous snags which they display in colder countries. In these respects it approximates the characters of the Indian deer; and would lead one to conclude that the stag is very general on the eastern continent, only in the course of years it has been much modified by difference of climate.

We must not infer from the vast number of stags' horns which are found in a fossil state, that there has been an equal number of stags; for, as they come to their full head at five years old, each furnishes fifteen sets of horns, if it lives to complete its twentieth year; and, therefore, making reasonable allowances for casualties, we may say that there are probably ten times as many sets of horns as there have been stags.

But still the numbers have not only been very considerable, but the stag, probably larger than at present, as already mentioned, must have been a very old inhabitant of many parts of Europe, and of these kingdoms among others; and he appears to have shared the fate of some other animals which have now perished as races, in certain catastrophes, the nature of which we do not, of course, very well understand; but from which a portion of stags escaped, perhaps, on account of their fleetness. In the cave of Kirkdale in England, in some parts of France, and in Italy, the remains of the stag are found, blended in one ruin with the bones of the elephant, the rhinoceros, the hippopotamus, the hyæna, and the bear; which is a demonstrative proof that the whole must have at one time been com-habitants of the localities where their bones are found. Hence there arises the curious question, to what circumstances, chemical or otherwise, is it owing that the elephant, the rhinoceros, the hippopotamus, and the hyæna, have perished, while the bear and the stag have remained to the present time?

It will be foreign to our purpose to enter upon the formal discussion of this curious question, which belongs fully as much to geology as to natural history; and for the geological solution of which the data are but scanty. But we may remark in passing that these curious charnel houses, which carry our thoughts to times long gone by, are all, we believe, contained in fresh water deposits; which abundantly shows that no ocean flood could have borne on its tide those animals which we now regard as foreign to the several localities; and as the elephant, the rhinoceros, and the hippopotamus are all semi-aquatic, found always low down—and as the hyæna is a burrowing animal, and neither it, nor any of the other three, is well fitted for flight; while the stag is fleet, and the bear can climb, we can suppose that these two animals could make their escape from a local flood, by which the others were borne to those entombments in which their bones are found. But what was the catastrophe?—So far as we can judge, there has not been one but many; and they do not appear to have been attended by the action of any cause which disturbed the solid strata of the earth, any further than perhaps mechanical laceration of the surface; and, generally speaking, if we search upward along the rivers near which those deposits are accumulated, we might trace something like the empty basin of what has once been a lake, which lake, by the bursting of its barrier, might have produced exactly the same kind of result with which we meet.—But we have to do with living animals, and not with the memorials of those that are dead.

In Britain the stag, which was once so abundant, is now very rare; and the few that are met with in England are objects of curiosity rather than any thing else; and, though royalty still keeps up stag hounds, stag hunting even by these is a most ungallant and even ignoble sport, a sport from which the "merry men" of old would have turned away in most baronically indignant. The deer is carted to the field, hunted to a stand still, and then carried home again; and thus ends the sport—equally unmeaning and unmanly.

In former times it was far otherwise; and nowhere is this most dashing of all exploits in the field described with more vigour or more truth of attention to the other animals incidentally mentioned, than in Scott's beautiful national poem, "The Lady of the Lake."

We shall quote a few lines of the opening:—

The stag, at eve, had drank his fill,  
While danced the moon on Monan's rill,  
And deep his midnight lair had made,  
In lone Glenartney's hazel shade;  
But, ere the sun his beacon red  
Had kindled on Ben-Voirlich's head,  
The deep-mouthed bloodhounds' heavy bray,  
Resounded up the rocky way,  
And faint, from farther distance borne,  
The echo of the hoof and horn.—  
Yelled on the view, the opening pack,  
Rock, glen, and cavern paid them back.  
To many a mingled sound at once  
The awaken'd mountain gave response.  
A hundred dogs bayed deep and strough,  
Clattered a hundred steeds along;  
Their peals the merry horns rung out,  
A hundred voices joined the shout;  
With whoop! and hark! and wild halloo!  
No rest Ben-Voirlich's echoes knew.

Far from the tumult fled the doe;  
Close in her covert cower'd the doe;  
The falcon from her cairn on high,  
Cast on the rout a wondering eye,  
Till, far beyond her piercing ken,  
The hurricane had swept the glen.

Considered merely as poetry the passage which we have quoted is very beautiful; but Scott had so keen an eye and so warm a heart to every scene and every production of nature, that it was only with him to glance at a subject, and it instantly became enveloped in a flood of light. We have the habit of the stag quaffing the clear stream by moonlight. "The hart by water brooks;" next we have him plunging into the forest for his nocturnal repose. Then at grey dawn we have the whole cavalcade of the hunters to horse; and the bloodhound sent forward to find the slot, and track and start the deer. But for this part of the business we must refer to the article Dog. The hunt hurries forward after the staunch deer finder; but not a hound gives tongue till the game is in view; when the whole open like thunder; and it is hurry scurry, and neck or nothing if the ground is in a state of nature. Nor is the character of the other two species of deer given with less truth; the roe on the mountain top speeds off like the wind to those cliffs where no bloodhound could track him, nor pack run him down. On the other hand the doe, or female of the fallow-deer, a feeble and frightened creature, crouches down among the bushes, as if to escape by her insignificance from that fate from which her limbs are unable to bear her away. Last of all we have the falcon, perched securely on the rock, and equally safe in mountain castle, and her impetuous wing, looking down in utter astonishment, and contempt if you will, at all this coil and clatter among helpless and ignoble creatures, who must be content with walking and running on the humble earth, while she can cleave the air as swiftly as an arrow.

In different parts of the world, as we have already mentioned, the stag varies in size as well as in colour, but its average height is about three feet and a half, and its general colour reddish brown above, and whitish beneath, with some black about the face, and a list of the same down the hind part of the neck and between the shoulders. The greatest known weight of a British stag is that of one which was killed in Aberdeenshire, namely, three hundred and eighteen pounds, exclusively of the entrails, head, and skin. It is alleged that, in Bavaria, the animal frequently exceeds this weight. In Siberia, and some parts of America, it is usually of very large dimensions; whereas in China, Corsica, and some other parts of the world, diminutive varieties are found, which, in bulk, scarcely exceed a dog of ordinary size. Indi-

viduals also occur of a very dark or blackish brown, some of a light or yellowish brown, and some entirely white. The usual number of branches on the horns of a well-grown stag is six or seven, but some have more, and one variety is characterised by the superior amplitude of its horns. In most cases, the males only have horns; and after their sixth year, when they arrive at maturity, they shed them annually in spring, when they seek the most retired places, and feed only during the night. The annual reproduction of these appendages constitutes, in many points of view, one of the most remarkable phenomena of animal physiology. First, it affords a most striking proof of the power of the nutritive senses, and the natural growth which depends on it in warm-blooded animals, since the horn of a stag, which may weigh twenty-five pounds, is completely formed in ten weeks; secondly, it exhibits a singular instance of a limited duration of life in a part of the system, entirely independent of the life of the whole; and thirdly, it manifests a change of calibre in particular vessels; for the branches of the external carotids, which supply the horn with nourishment, are remarkably dilated during its growth, and recover their former area when that process has ceased; fourthly, it bespeaks a peculiar sympathy between the growth of the horns and the generative functions; because castration, or any essential injury of the organs of generation, impedes the increase, alters the form, and interrupts the renewal of the horns.

There are certain technical names given to the stag, according to his age, which are worthy of being noticed. The young, whether male or female, is styled a *calf*, and for a few months there is very little distinction between the sexes. At the age of six months, the *bossets*, or rudimental horns, begin to appear in the male, but they do not advance farther that year than two cylindrical knobs. In the second year they are longer and pointed, in which state they are spikes or dags, and the wearer of them is called a *brocket*. In the third year the horns put out two or three *tynes* or branches, and the deer becomes a *spayad*. The crown, or *surroyal*, appears on the top of the beam the fourth year, and then he is a *staggard*. The fifth year he becomes a *stag*, which is the only year that he technically retains the name of a species; for the sixth year he becomes a *hart*, and so remains for the rest of his life. In the sixth year he is called a *hart of ten*, when he is considered still too young for being legitimate game; but after his seventh year he is said to be *croched*, or *palmed*, or *crowned*; after which he is fair game. The number of snags or tynes in the crown of the horn seems to depend a good deal on the richness of the pasture, and on their having proper shelter and food during the winter. In former times, specimens were found, both in England and in other countries, with more than thirty snags on the crown of each horn; but we believe that half that number is of comparatively rare occurrence.

The female passes through a succession of stages as well as the male, but they are not so important; and, besides, regular sportsmen never make game of the females. The female of the first year is a *calf*, of the second year, a *brocket's sister*; and the third, and ever after, a *hind*.

Stags do not *new* or shed their horns immediately after pairing, though there is reason to believe that the decay of the horn begins at that period. The

crowned harts are the first to shed theirs, and always the older the earlier. Something depends upon the season and the pasture, but the average time may be reckoned about the end of February. The harts often shed theirs a month or six weeks later, and the younger ones a month or six weeks later still. The technical word for the horns is *attire*; and when these are shed, the animal is said to "lose his attire." In this state he is comparatively defenceless, and retires into the shadiest parts of the cover, or into the most remote or unfrequented parts of the pasture, where there is no cover. He remains there during the summer, and about the month of August the horns are completed; and he clears them of the skin of velvet with which they were covered, by rubbing them against trees or rocks, or against the ground. The hind is in retirement in a different part of the pasture during the same time, where she attends to her calf with truly maternal solicitude, and shows considerable address in drawing off any apparent danger from the place where it is concealed. The young of the former year and the brockets form a third association, but they also retire when they shed their horns.

In the rutting season the harts fight desperately with each other, but it is only when two of the same age come into contact with each other that this occurs, for the weaker always gives place; and indeed there seems to be a provision of nature to prevent these rencontres, for the fury of the rutting season comes upon them in the order of seniority, which is also the order of strength. In their battles their horns often get so entangled, that the two are thereby held together till both perish. The great agitation into which they are thrown at this period completely exhausts them, which is not to be wondered at, when we consider that they abstain almost entirely from food, and run about the pastures "routing" or roaring, as if they were mad. Immediately when the stimulus is over, they withdraw in a state of great exhaustion, and remain quiet, eating a great deal, especially acorns, if they can find them; and this is the reason, probably, why they attain a larger size in oak forests than in forests of pine, or on the open hill; and it may in part account for their superior size in former times both in Britain and on the continent. In England, those noble animals are, as we have already hinted, comparatively few; but the case is different in the mountainous parts of Scotland, especially in the central Grampians, between Athol on the south, and Badenoch and Strathspey. There are a few in the south-western Grampians, and also in the mountains northward of Lochness; but there is nothing which can be considered as a deer-forest in either of those places, or anywhere in Scotland, or, we may add, in Britain, except the forest of Athol, or, more strictly speaking, the forest of Minigag. The eastern part of that forest contains some of the loftiest mountains in Scotland, and it gives rise to various branches of the rivers Dee and Don towards the eastern side, of the Spey towards the north, and of the Tay, more especially the Bruar and the Tilt, towards the south. There are extensive natural forests of pine in the upper glens or valleys of the eastern rivers, but the deer are not quite so abundant there as they are in the south, where the exposure is warmer and the pasture better. Glen Tilt and Glen Bruar, especially the former, are the principal winterings; but

the deer, if all together, have a range of not much less than 100,000 acres of hill, and on this there are certainly not fewer altogether than 7000 or 8000 head, old and young, the greater part of which are the property of the Duke of Athol; and the great hunts, or rather slaughters, most frequently take place in Glen Tilt, though the more laborious operation of "deer-stalking" is pursued in other places. On the great hunts, they are driven by a circuit of people, who bring them to a pass or narrow, where the marksmen are posted, so that they can select and make sure of their victims. This is not a very manly sport, but it is very efficient "pot" hunting; and the nature of the ground renders it impossible to adopt any more sportsman-like mode.

It is understood that, from the care bestowed upon them by all the proprietors, red deer are becoming more numerous on those mountains; and though the hill is quite open, and the keepers are but few, there is comparatively little poaching; and, indeed, it is rendered unnecessary, because the deer are always straying so far out upon the spurs of the hills, that any one who is so inclined may occasionally have a shot; and to attempt shooting deer on the open Grampians, as a matter of profit, is nearly out of the question.

When poaching is attempted, it is generally in the winter, or in the latter part of the autumn, which usually has all the horrors of a very severe winter in those exposed and upland places; and there have been instances in which adventurers, who went to spend the night on the hill for the purpose of obtaining deer illegally, have had the most terrible justice executed upon them by the storm. The snow storms on those mountains nearly rival in violence the "temporales" of the Andes: the snow makes the air as dark as midnight; and the wind drives with the voice of thunder among the crags, and sweeps the waste with the force of hurricanes, so that men are rolled before it like chaff, hurled over some precipice, and lost,—until the crow and the raven point out the place of their bones in the ensuing summer; for the snow in which they are buried in great part preserves their bodies to become food for these dark and dusky-coated scavengers of the desert.

Such is the situation and character of the most extensive forest of red-deer which now occurs in this country. In England there are remains in some of the royal forests, and perhaps in a few other places, but they are comparatively few, and do not stamp the principal character upon the locality as they do on the Grampians.

**FALLOW-DEER** (*Cervus dama*). This species is smaller, feebler, and more tame and common-place in all its characters than the stag. There are no canine teeth in either sex. The male only has horns, which are round in their section, with two pointed antlers, and the summit palmated lengthways. The colours are variable, but they are in general brown, dappled with white. The horns of the male fallow-deer, or buck, are divergent, terminated above by a flattened longitudinal palm, toothed with what are termed *advancers*; the base of the beam round, with basal and median, or brow and bezantlers, pointing forward. It has no canine teeth, and the nose is terminated by a muzzle. In size it is inferior to the common stag. In summer both sexes have the back, flanks, and thighs, of a fulvous-brown colour, diversified with numerous white spots. In winter these parts are wholly brown; the

buttocks are always white, with a black streak on each side; the tail is longer than in the stag, reaching to the houghs, black above, and white below; a dark line passes along the back; the belly, inside of the limbs, and under the throat, white; the head, neck, and outside of the legs, reddish grey.

Fallow Deer.

The male of the fallow-deer is usually called a buck, the female a doe, and the young a fawn. The buck fawn has no appearance of horns the first year, but they come up in simple snags the second, at which time it is a *pricket*. The third year there are two branches, and the palm begins to be formed on the top of the beam; but it is not properly formed till the fifth year, when the animal becomes a buck of the *first head*, which answers to the stag of the former species. The horns have now attained their principal shape, except on the margins of the beam, where they every year acquire additional snags, which are called *spillers*, or *advancers*, but they continue to increase in size. As is the case with the stag, they drop their horns in the spring, and both that operation and the rutting comes on about two weeks later. The period of gestation in the doe is eight months; she becomes fertile the second year, and ceases to be so about the fifteenth. The fawns, at a dropping, are one, two, or three, according to circumstances.

Fallow deer are gregarious; but the bucks live apart except during the rutting time, and in winter, when most gregarious animals live indiscriminately. Where the herd is large, it is, however, generally divided into packs, each under the guidance of the oldest or most powerful buck. This species is so well known as the common park deer of Britain, that a minute description of it is not necessary. It is not known, and probably never was known in a totally wild state in this country; and this in part accounts for the diversity of colour we meet with. In the south of Europe it grows to a much larger size than with us; and hence it has been supposed that it is native there; but the point is not fully ascertained, and it may be an importation from the west of Asia. In the central countries of Europe, wild ones are few, and there are none to the northward of the Carpathian mountains. But in all parts of Europe, where there are extensive parks, there are fallow deer in a

state of semi-domestication ; and where there is cover in the neighbourhood, they often escape in such numbers as to become an annoyance to the farmers.

The flesh of the fallow deer is understood to be more delicate and juicy than that of either of the wild sorts in this country ; and it is in consequence in high request as a luxury. The animals themselves, though destitute of the grandeur of the stag and the gracefulness of the roebuck, are very ornamental in parks ; and where undisturbed, they are very tame and gentle throughout the greater part of the year, and not nearly so formidable in the rutting season as stags. The sound of their voice is low as compared with that of the others, and it gets the technical name of groaning. Bucks when hunted do not take the country in breadth as the stags do, but run in circles, and very frequently take the water, though they are not such bold swimmers as the stag. The chase of them, both from the grounds they frequent and from their own characters, is not so strikingly effective as that of the stag, but it requires more care, as they are apt to throw out the hounds and leave them at fault.

Though the existing fallow deer appears to be a native of the south, at least of the south of Europe, though certainly not of tropical countries, yet the large deer, of which the remains are found in the fresh water deposits, are usually referred to this species, or at least to one resembling it, on account chiefly of the form of the horns ; and it is a little puzzling that the fallow deer which appears to have a more southerly habitation than the stag, should have palmated horns, approaching more nearly to the character of those of the polar deer than those of the stag do ; but, as is the case with all animals which have been very long in a state of total or partial domestication, and which accompanied men in their migrations from country to country, it is by no means easy to ascertain whether the fallow deer has degenerated in size from the fossil specimens, or whether its horns may not have altered their character from being simply forked as most of those of the deer in warm countries are, to that palmated form of the upper parts of the beams which they now display.

The ROEBUCK (*Cervus capreolus*). This is the most light and handsome of all our deer ; and in some respects it approaches the antelopes, the ancients giving it and some of the species of that genus indiscriminately the name of *Dorcas*, that is "bright eye ;" no lachrymal sinuses, scarcely any tail, the colour a greyish yellow, varying more to reddish or brownish, but always with a large white disc on the buttocks. The horns are rather small and cylindrical, with a small antler on the middle of the beam pointing forward, and a second one higher up and turned to the rear. The roebuck is pretty generally distributed, being found in all the temperate parts of Europe and Asia, and even it is said in India, though there it has been confounded with some of the Indian species which resemble it a good deal in the forms of their horns. This is the smallest species in Europe, not exceeding four feet in length, and standing about two feet high at the shoulders. There are coloured varieties, one very red, and another yellowish brown, and a third nearly black ; but they all have the characteristic white disc, at least in the winter, and the tail is never more than an inch in length. Their summer and winter clothing differ a little both in colour and in texture. In winter the fur is completely soft

and tinged with grey on the neck and head, and the disc is much less conspicuous ; but in winter the hair thickens and hardens, and the colour deepens, especially on the upper part.

The manners of the roebuck are different from those of the species hitherto described. They are not gregarious, and therefore do not make the same appearance in proportion to their number as the deer. The male is also monogamous, and remains attached to one female for life, the two keeping company, or at least being near to each other all the year round, and the rutting season not being accompanied with that violent excitement which takes place in the others, more especially in the stag.

The period of gestation is also different, and so is the time of shedding the horns in the male. Rutting time is in the beginning of November, and the female goes little more than five months, while the fallow deer goes eight months, and the hind a little more. The pairing is thus about two months later than in the others, and the fawns are dropped about two weeks earlier. The male also sheds his horns soon after the rutting time, and acquires the new ones during the winter, so that he is in his apparel for a much longer period of the year than either the hart or the fallow buck.

The doe drops two fawns, for which purpose she retires into the closest cover that she can obtain, but at the end of about two weeks she makes her appearance with them in company ; but she hides them if danger appears, and shows considerable address in enticing enemies away from the place of their concealment. They are generally, if not invariably, a male and female, which continue with their parents during the summer ; but previous to the rutting time they are driven off to shift for themselves, and to keep company with each other for life, which is from about twelve to fifteen years, if no casualties occur ; but as roebucks prefer the open hill to the shelter of the forest, many of them perish in severe winters.

They are much more destructive to young plantations than either the stag or the fallow deer, as they prefer the tender twigs and buds of these to grass ; but they are lively and vigorous creatures ; and few sights are finer than that of a roebuck bounding among bushes, or up a hill side among tall heather. This plant is often as tall as himself, so that when he alights he is concealed, but at every bound he rises to some height clear of it, and puts one in mind of what is stated of the antelopes in the coppices of Southern Africa. The roebuck leaves a strong scent ; and therefore he is more easily found than the stag, where stags are not numerous ; but he is not more easily caught. As the stag runs out, he is sure to fatigue himself ; and though he recovers if he can reach the water, and makes a formidable resistance when he stands at bay, yet, if the dogs are staunch, and the ground practicable, he is almost sure to be taken ; the roebuck on the other hand shows artifice : he dashes off at first, but if pursued he doubles, bounds sideways to some cover with immense leaps, and with the velocity of a bird, and couches down till the chase pass him, and then, bounding from his cover, he is off in another direction. The same roebuck has been known to be hunted through several counties ; and of these one is mentioned by the late Mr. Bewick of Newcastle. It had been hunted out of Scotland through Cumberland and various parts of the north of England, and at last took shelter in the copses on

the Tyne; there it was frequently seen, and as frequently hunted. But no dogs could come up with it in speed; and its arts were equal to its agility, as it swam the river, or in some other way escaped. The chasing was continued during the sojourn of a very severe winter; and upon one occasion it crossed on the ice, and by so doing was so much strained, that it was easily taken alive. After being kept for some weeks in the house it was again turned loose, but all its enterprise and all its cunning appeared to have left it; for after being chased only a little way it lay down in the middle of a brook, and was killed by the dogs. This anecdote shows that the peculiarly elastic character of the roebuck is quite incompatible with domestication. It is also very difficult to confine this species within enclosures, in consequence of the height to which it can leap; and as its flesh is not considered quite so good as that of the others, and farther, as there is not so much of it, it is left in a great measure to its native freedom on the hills. It should seem that the roebuck by being less excited in the rutting season than the others does not come into such high condition preparatory to that season.

In England, roebucks are now very rare; and as there is cover for them in most of the places where they might be looked for, they are not easily found. In the Scottish mountains, however, they are more abundant, though scattered, and rarely seen more than one at a place at the same time. They are not met with in exactly the same places as the red deer, but rather where there is an admixture of hill and rock and copse. They are also, at certain seasons of the year, met with further down than the red deer generally are, but they do not hesitate to take an occasional dash into the inhabited parts of the country when the winter is very severe on the hills; but on these occasions they generally have all their arts about them; so that it is but a passing sight which one can obtain. It is also more difficult to get a shot at a roebuck than at a red deer. In Scotland they are found as far north as Sutherland and Caithness; but their chief haunts are in the neighbourhood of those places which have been described as abounding most with red deer; only from the peculiarity of their manners, and the fact of their feeding in the copse and on the twigs, rather than browsing the herbage, they are not often seen, to which their habit of lying close till the danger be passed, contributes still farther.

There is no account of the horns of the roebuck being met with in the same accumulations as those of the other deer in this country; but they have been found in some parts of France, though it is said that there are some peculiarities in the fossil remains which are not found in the living animals; and thus, though there is a similarity established, there is not a perfect identity, so as to warrant us to conclude that the roebuck of our times existed and inhabited at the same period and in the same country with those now extinct animals the *Paleotherium* and the *Mastodon*, whose remains are found in the same accumulation of peat, near the river Somme in France.

Such is a short account of the three species of deer which are met with in the wilds or in the parks of our own country; and they are the ones whose manners we have the best access to study.

THE AHU, or Tartarian roebuck—*Cervus pygargus*. This is the roebuck of the middle latitudes of Asia, and of part also of the east of Europe. It is a larger animal than our roebuck, and differs from it in having

the hair longer, and the horns more developed, and more furrowed and tuberculated in their basal parts. It is very generally distributed over the margins of the waste, from the mountains which divide Persia from the central countries of Asia, to some distance into Siberia; but it is not found in those parts of that extensive region which have a decidedly polar climate. In the summer season it keeps to the mountains, among the cliffs of which it bounds with great vigour; but in the winter it descends to the plains.

Like the roebuck it has no lachrymal sinuses, and the tail is still more deficient; being nothing more than a mere tubercle. The colour on the back is brown in summer, and that on the under part is yellowish. On the hinder part of the thighs and around the rudimentary tail, there is a disc of white, larger and more conspicuous than in that of the roebuck; and this mark is constant amid all the varieties of colour in the individuals, and all the changes from age or climate; and the old and young, and also the summer and winter appearances are so different, that animals in these states have been described as distinct species. A space round the nose and sides of the under lip is black, but the lips themselves are white; and those characters also remain constant.

The hair of this species is exceedingly thick, more so, perhaps, than that of any other. In summer it is stiff and erect, allowing the air to reach the skin, notwithstanding the great thickness of the covering. In winter it gets shaggy, and falls more closely on the body, forming a very warm covering. It does not appear that at this season it gets any of that long intermixture in its coat to which the name of "snow hair" may be applied without much impropriety; but its general coat becomes dry and bleached to a hoary colour at the points, which answers nearly the same purpose.

In all the field animals of central Asia, from the Himalaya northward, there is some provision of this kind; and the great change of seasons to which this part of the world is subject, is at once the necessity and in all probability the cause of this provision. In summer, the heat is excessive; and the plains are completely burnt up, so as to wear the aspect of vast floors of indurated clay; and at that season there is no rain except on the mountains: and as the last plants upon the margin of the desert, or in that kind of shelter which makes an incipient desert of the whole country, are always of a saline nature, the ground is covered with saline incrustations. It is at this season that such animals betake themselves to the mountains, while the wandering horde of Tartars with their cattle, move farther to the north, and reach the lower parts of the plains or *steppes*, where there is still some moisture to be found.

In winter the cold is as proportionably severe as the heat is ardent in summer; for in plains the elevation of which is not great, and which lie on the same parallel of latitude with the south of Italy, and the centre of Spain, where snow is rarely seen upon the plains, and where there is very seldom ice upon even the shallow pools, the rivers are so completely frozen over, as to afford pontage to the inhabitants.

So great a difference between the summer and the winter naturally produces a corresponding difference in those animals which, like the alm, are freely exposed to the weather all the year round; and this climatal difference is quite sufficient to account for all the external differences which are traceable between

this roebuck of central Asia, and the roebuck of Europe. As we are not very intimately informed on the subject of the natural history of this part of the world, it has not been ascertained with certainty that the manners of the animal under notice correspond exactly with those of the roebuck of the west; but the structural resemblance, we may almost say identity, is so great as to leave little doubt upon the point. It is probable that this animal is found over the greater part of the high lands in Asia, and that it is modified in its coat in different parts there to as great an extent as the difference between it, as described in the south of Siberia, and our roebuck; and what gives more probability to the supposition of its being but one species from India to Britain, is the fact that in the milder climate of India, there is nearly the same deviation from the Tartarian type as in the milder climate of Europe. Our roebuck is smaller than the Tartarian, shorter and smoother in its coat, and with the horns less developed. The Indian variety is described as being still smaller than ours, more smooth in its coat, and with the horns less developed. These circumstances would lead us to infer that the roebuck is more generally distributed over the eastern continent than any other of the larger mammalia which remain in a state of nature. There is still, however, a good deal to be done in order to trace the connexion between the different localities in which it is found, and to mark the gradation by which the characters of the one locality run into those of the other. But these points are not impossible, for they only require observation; and as it is highly probable that lines of communication may soon be opened up through central Asia, we shall not much longer remain in such deep ignorance as we are at present respecting that portion of the country which may be said to connect the four distinct characters of land and climate of which Asia is composed. Siberia sloping toward the northern sea, China to the eastern, India and Persia to the southern, and the central countries of Asia toward the great salt-lake of the Caspian. All these four are very different in their different characters, and in their vegetable productions; and therefore they must produce corresponding modifications in the characters of animals; and if we could once see clearly how one species, such as the roebuck, common to the whole, has been modified by each, we should be furnished with a key to much of their natural history, the knowledge of which we never can obtain by local and individual observation, however assiduous and however accurate. Nor would the information be confined to the present time only; for as it is well ascertained that the roebuck has inhabited even the west of Europe along with some of the lost animals, and as the fossil horns resemble those of the Asiatic more than the modern roebuck of Europe, this species, well made out, would be at least one means of carrying our knowledge backward to the time when they existed.

The NEPAL STAG—*Cervus Willichii*. This species is found in the upper valleys of the Himalaya, and partakes partly of the characters of the common stag, and partly of those of the roebuck; but more of the former. The horns are circular in their section, each is furnished with two brow antlers turning upwards, which with an additional snag higher up the beam, form a sort of bifurcation. The beam rises with a contrary flexure, bent backwards, and then slightly forwards. The size of the full-grown animal is large; the colour

on the upper part yellowish brown; lachrymal sinuses large; the ear short and broad, the tail very short, surrounded with a very large white disk. The legs fawn colour, the hoofs black, very fine in their texture, and sharp pointed, resembling those of the mountain antelopes. The history of this species, its habits, the change of its colour, and the texture of its fur with age or with seasons are, however, very imperfectly known. Its most remarkable external character is the position of the disc, which is more above the tail than below it, whereas the contrary is the case in most of the other species.

In the south of Asia and the Asiatic isles, there are two distinct groups of the genus *Cervus*, which differ in some respects from the deer of Europe, and the different members, whether we are to consider them as species or as varieties, which compose each group, have certain characters in common which enable us to generalise and thereby shorten, at least, a part of the descriptions of them. As these are known only in Asia, at least, as native animals (for some have been imported into Europe in the living state), we can describe them only by their names as known to naturalists. The one group is styled *Rusa* and the other *Axis*, which we shall shortly notice in succession.

*RUSA*. The general characters of this group are: the horns round, with a brow antler and a single snag near the tip, but without any bas-antler or branch on the middle; they have a broad muzzle, and large lachrymal sinuses. The males have canine teeth, and rugged manes; the tail is also longer than in any of the European deer; and some of them at least are of larger size. They are the upland or woodland deer of India, and the larger islands of the East; and in their manners they in general more resemble the stag than any other of our species of deer. There are several species of them named in the books; but some of them are known only as museum specimens. It is certain, however, that the animals are very plentiful in the tangled and unfrequented parts both of India and of the islands. Indeed, it is probable that some of the species may inhabit the southern side of the mountains considerably to the westward; for one is mentioned by Aristotle, of the size of a stag, and with a mane on the withers, and a horn resembling the roebucks.

The GREAT RUSA—*Cervus hippelaphus*. This is one of the species the habitat of which is not very well known, though it is probable that it exists in many parts of continental India; but the specimens which have appeared in Europe have been obtained from the islands, chiefly from Java. The hair is coarse and hard; and, after the first year, that on the throat, cheeks, and neck, is long and shaggy, the latter forming an erectile mane. In summer the colour is yellowish, and the disc on the buttocks nearly obliterated, but in winter the colour on the upper part becomes gray-brown, and the disc becomes more conspicuous. Different specimens have, however, varied so much in their colours, as well as their size, that the species is not very well made out.

The SAMVER OF BENGAL—*Cervus Aristotelis*. This species is much better known than the former, being met with in many parts of India, especially in the valley of the Ganges. Its characteristic distinction taken from the horns, is that of having the branch or second antler very far up upon the beam, and turned to the rear, instead of forming a fork with the tip of the beam, as in most others of the group.

Malayan Rusa .

Rusa of the Marianas .

The burr of the horn is very broad and pearly; the first antler is cylinder-shaped, strong and straight, and stands nearly vertically upon it, measuring about ten inches in length; the beam bends from the back of it obliquely outwards, and to the rear, and with a sweep turns its point backwards; near the summit, or at more than two-thirds of its length, is the second posterior and internal branch, short and pointing upwards. In the British Museum there is a specimen measuring about twenty-three inches, which is very rugous and robust. The horns stand upon a broad and short pedicle; the face is straight, the nose pointed, the muzzle small, and the suborbital opening is very considerable. The ears are broad, with white hairs standing up around the orifice; the tail is black, reaching half way down the ham, and is well furnished with hair. The throat and neck are covered with long coarse dark brown-grey hair, reaching partially over the shoulders, susceptible of being raised like a lion's mane, when the animal is excited. The shoulders, head, back, rump, and buttocks, are dark-brown in summer, and almost black in winter; outside of the ears sepia; the belly whitish, as also a ring round the nostrils and mouth, separated from the brown by a deeper shade, which spreads up the face; the inside of the limbs and legs fawn colour, darker over the knees down the front; the breast is black. The male is nearly the size of the elk, and indeed is so named in India by the British sportsmen. They represent him as being excessively strong and vicious. Some of them, on a shooting expedition, had crossed an arm of the Jumna to a woody island in quest of game;—they were on the back of an elephant, and entering the jungle suddenly roused an old male of this species. On seeing the elephant he started up with a long shrill pipe or whistle, which caused others to rise and dart into cover, while he stood at bay with his bristly mane on end, in a most threatening attitude: but before the sportsmen could prepare proper shot, he wheeled round and dashed through the underwood with the facility of a rhinoceros. Captain Williamson evidently met the same species. He describes the stag as arriving at the size of a Lincolnshire cart-horse, fifteen or sixteen hands high, shining black, with tanned points (of the hair?) One of these, he says, heads a score of females, who are of a mouse colour. He likewise calls it an elk, and adds, that they reside in the Prauss jungles. But though this species gets the name of the elk, there is no resemblance between them, farther than the generic character. This is decidedly a species of the warmer climates; and though we are but little acquainted with its habits in wild nature, it does not appear to be so social as the elk; indeed, the deer of warm countries do not in general appear to congregate in such numbers as those of temperate and polar climates.

**MALAY RUSA**.—*Cervus equinus*.—This is also a large species; and though the specimens hitherto brought to Europe have been obtained from the Sunda Islands, there is every reason to believe that it inhabits the Malay Peninsula, and probably also some parts of India. When full grown, it is described as being of the size of a horse, with the horns tapering, and the second snag, which is turned to the rear, very small. The horns are of a very bright reddish brown; both sexes have canine teeth; and the frontal bone is much flatter than in most species of deer. The colour is greyish brown, paler on the under part; rust colour on the haunches, and the tail; the insides of the legs

whitish; the muzzle black, and the chin white. The following is Hamilton Smith's description of a specimen exhibited some years ago at Exeter Change.—“The animal was then about two years old, and his horns were simple, or in the bracket state; the next year its new horns showed the bifurcation of the summit, to be as in the Black Rusa of Bengal; that is near the summit on the internal posterior side. It was then four feet, or something more, at the shoulder; and still higher at the croup; its eyes were large, dark, and mild: the suborbital slit opened at pleasure, and was remarkably expanded when it drank, with a perceptible action of the air passing in and out as before noticed. The ears, broad and pointed, were nearly naked within, and whitish-grey without, the face, shoulders, back, and thighs were of a dark brown-grey; the hair rough and bristly on the neck and throat. This colour was darker, and the hair very long, especially the second year, when the crest or mane on the neck and throat hung very heavy and thick; the breast and belly were of a dark ash, almost black. A considerable disk of a clear rusty, or orange, colour, expanded over the buttocks, lined the inferior side of the tail, and was separated by a black line from the grey of the thighs. The tail, about a foot in length, was black above; the joints of the legs, the inside of the thighs, and their anterior side were yellowish dun, and the legs from the joints downwards buff; the chin was white, with a black spot at the corner of the mouth, on the lower lip, and a bar of the same colour above the nostrils, which were placed on a black muzzle; the cheeks and space round the eyes were buff, passing to grey.”

The horns are of a dark colour, rugous, robust, but shorter and less curved than in the *Hippelaphus*; the anterior antler, and posterior snag, are both short and obtuse, but from the size of the first, or bracket horns, of the animal being near eight inches long, it is presumed that they become, if not much prolonged, at least very bulky: his second horns were about fourteen inches. This species resembles the Bengal Rusa in many particulars: both have the forehead flat, and the face straight; the muzzle small, with spots of black on the under lip, and a ring round the nose; the ears naked inside; the horns short, stout, and similarly formed; the same mane and dark breast. In fact, the only obvious differences are the presence of a disk on the buttocks of the present, which does not appear on the former, and that of dimensions; but even in this particular there can be no great disparity. It may be, therefore, that ultimately these two will be marked as only varieties of one species.

There are some other species or varieties described as inhabiting the Malay peninsula, or the adjacent isles; but it is by no means unlikely that some of them are the females of the species now described: and, indeed, there is some reason to suspect that all the Rusas are merely climatal varieties of one very widely distributed species, which may be called the stag of South-Eastern Asia, or the Indian stag; we shall, however, mention two others, which differ considerably from those which have been enumerated, and which are the most remote from continental Asia in their localities.

**THE MARIANA RUSA**.—*Cervus Marianus*. This species inhabits the group of the Mariana or Ladrone islands, which lie between twelve and twenty degrees north latitude, and a hundred and forty-four and a hundred and forty-eight east longitude. There is every

reason to believe that it is not originally a native of those islands, but has been imported from the continent of Asia, probably from China. A specimen was brought to Paris, by Quoy and Gaimard, in Freycinet's voyage of discovery, of which the following is a description:—"It is more robust, but not much taller than the roebuck, with round divergent horns standing on a low pedicle, having two antlers, the basal nearly vertical, and at its junction with the beam a small process, not unlike a trilobed tooth; the other is posterior and internal, and compared with the size of the head, the horns are large and heavy, being about thirteen inches long; their colour is ashy, and they are extremely rugged. Between the horns the skull has a longitudinal eminence, and before the orbits, near the base of the nose, are two longitudinal convexities, very remarkable, and the species is destitute of canines, by which character it approaches to the true axis; the face is almost black, with a streak running down from the horns, between the eyes, to the nose; the muzzle small and black, and the colour of the whole body dark brown, slightly mixed with grey, at least such are the colours now discernible, the specimen being in a bad state of preservation; the tail is about four inches long, and black. A fawn brought from the same island in the above museum is fulvous-brown, without spots; the throat is whitish; a white spot at the end of the lower jaw, and one at the base of the ear. The inside and anterior border of the thighs and buttocks are white, and the legs buff." This species, like most of those of the islands, is described as being very tame and gentle in its manners, which gives additional ground for supposing that it is not an aboriginal animal, but has been carried to the islands from continental Asia.

**RUSA OF TIMOR—*Cervus Peronii*.** Only the head, we believe, of this species has been brought to Europe; and from the little acquaintance that we have of the interior of the island of Timor, nothing is known of its habits in its native country. It is understood to be smaller than any of the rest of the group, dark coloured, with slender horns, and the second snag forming a more regular fork with the tip than in the other species of the group. This is the most southerly inhabiting deer in all the eastern continent or its islands; for the next land which we meet with to the south of Timor is New Holland, in which there are no deer, except such as may have been very recently imported by the colonists.

**AXIS.** The animals of this group stand nearly in the same relation to the fallow-deer of Europe, as the rusa do to the stag. They are smaller in size, and less vigorous in structure; they have no canine teeth, and their skins are, generally speaking, dappled with white spots. Generally speaking, they inhabit lower down than the deer formerly described.

**THE SPOTTED AXIS—*Cervus Axis*.** The chief distinction between this species and our fallow-deer is in the form of the horns, which are round in their section through and without any palm. The horns stand nearly vertical, only with a slight bend forward, and the points inclined towards each other. They have a basal antler pointed forwards, and another on the middle of the beam turned backwards; the muzzle is black, and there are no lachrymal sinuses. There is, indeed, so much resemblance between this species and fallow-deer that when their horns are shed, it is difficult to distinguish the one from the other. The chief marking colour is in the dorsal line, and the disk on

the buttocks. The dorsal line in the axis is very deep-brown, and marked with white spots, while that on the fallow-deer is paler, and has the spots only on the margin. The disk in the fallow-deer is white, that on the axis is yellowish. The two sexes are also more equal in size than the fallow-deer, the female being larger than the doe, and the male not larger than the buck. There are, however, considerable varieties both in size and in colour.

Axis Deer.

These deer are very plentiful in the lower districts of India, where they inhabit the margins of the jungles; they are known by the general name of hog-deer, and are much prized by the sportsmen of the east. We believe they are seldom met with in the countries above the Ghauts, or passes of the mountains, as the large deer are seldom met with below; and, indeed, in all their characters, and in all their habits, they correspond so much with fallow-deer that, notwithstanding the different form of the horns, it is difficult to refrain from considering them as the same species; and, perhaps, as the parent stock which has supplied the fallow-deer to the western world. Several varieties have been described, but they appear more accidental than otherwise, so that it is unnecessary to mention them particularly.

There is still another group of deer, belonging to the south-east of Asia and the Oriental Islands, which have very peculiar characters, and which are decidedly distinct from any of the rest. Their most remarkable characters are, that the males have the horns upon peduncles, which can be traced upon prominent ridges down the forehead almost to the nose and canine teeth in the upper jaw, which are so long that they protrude beyond the lips. They have also very deep lachrymal sinuses. The tongue is very long, and they can protrude it upwards as far as the eyelids. They appear to be intermediate between the deer, properly so called, and the musks; and it is doubtful whether they shed their horns seasonally like the other deer. They have been brought chiefly from the Sunda and Philippine islands; but there is also a species in Nepal. There is some difficulty about the different species, but there seems no doubt that several of them are distinct, and those which are obtained from the Philippine islands, from the Sunda

islands, and from Nepâl, are all different from each other. They are elegantly formed creatures, and, notwithstanding their produced canine teeth, they have a very mild and gentle aspect. The following is the description of the Sumatra species or variety:—

The body is compact; the legs remarkably fine and slender; the muzzle is rather broad; and the canines assume the form of inverted tusks, sharp at their points, turned towards the animal, and outwards. Two rib-like eminences ascend from above the nose over the eyes, and, elevating themselves from the head, in the form of slender pedestals, to the height of two and a half inches, terminate in a flattened summit. Upon these the horns are placed, about three or four inches long, forked at top, with the points turned inwards, and with a small branch at the base pointing forwards; between the ribs the skin of the face is doubled into a fold, which has the appearance of a third or central rib; the fur is fine and close, of a greyish brown, paler beneath; the breast, inside and anterior face of the thighs, are whitish; the tail is short, dark above and white below.

The Malay name of this animal is *Kijang*, or *Muntjak*, the latter of which has been adopted as the specific distinction. They are understood to live in pairs, in the same manner as the roebuck. Several varieties of them have been imported from Sumatra, from the Philippines, and from other parts of the Indian Archipelago, the history of which is not very clearly made out: but the following is the description of one from the Philippine islands:—"The peduncles and the horns are about one-fourth the length of the head, and thicker than those of the *kijang*, and the ridges which terminate in them extend down only as far as the eyes. The rest of the face is flat, with the forehead slightly arched; there is a dark streak on the anterior base of the pedicles, and between them the hair is black, forming a spot with the point downwards, and leaves a crescent of a dirty buff between them; this colour spreads round the orbits and on the cheeks; the lachrymal sinus is dark; the ears rather short and obtuse, whitish within, dull buff outside; the colour of the coat is wholly brown sepia-grey, clearer on the throat, and darkest on the neck and eyes; the tail is three inches long, black above and white beneath." There are several museum specimens from the Oriental Islands, which appear to differ from each other; but as some of them are only fragments, their characters are not fully made out. There is one, however, of which a pretty distinct account is given:—

THE NEPÂL MUNTJAK, or Musk-deer of Nepâl—*Cervus moschatus*. In the Oriental Collections for January, &c. 1798, vol. ii., Sir William Ousley figures an animal, under the name of Musk-deer of Nepâl, from a drawing executed by a native artist, with the following dimensions, communicated by Colonel Ironside:—Length, from between the ears to tail, two feet four inches; height, two feet; length of head, seven inches; of the tail, six inches and three quarters; of the tusks, two inches and one-eighth; the hair bristly and thick, two inches long. By the illuminated plate, the animal must be entirely dull fawn colour, with the superior part of the tail alone dark; the horns, placed upon high pedicles, are dark, simple, without branches, and pointing to the rear; the limbs are very slender; the spurious hoofs small; the neck rather short. The habitat and character of the hair render it probable that it is a distinct species;

and although no reason is assigned for the name of musk-deer, that being the designation of the natives, render it probable that it is impregnated with a musky smell. Altogether, these are rather singular animals. The length of the canine teeth is a very remarkable character, and one which is somewhat puzzling, as, along with this armature of the mouth, the animals are remarkable for the gentleness of their manners. The fact of the horns being shed only once, or at most twice during the life of the animal; and if this is fully established, it will be sufficient ground for taking these animals out of the genus *Cervus*, and establishing them into one entirely peculiar; but, in the meantime, we want information respecting them. There is no doubt, however, that they have many peculiarities; and as they are found in so many parts of the East, and with different characters in the different localities, they may perhaps, when better understood, throw additional light on the zoology of the regions to which they belong. It is understood that they are gregarious, and very timid and gentle in their manners; that they do not live in large herds, but in small packs or families in the woods; and though they unquestionably partake more of the characters of the deer than of those of any other genus, they are undoubtedly very peculiar, and there are no animals in the east the more perfect history of which would be more desirable. This is the more to be desired, from the fact, that there does not appear to be anything analogous to them, either living or fossil, in any other part of the world. There are many points, however, in their structural history of which we are in a great measure ignorant, and which will require to be cleared up in a satisfactory manner before we can confidently decide whether they are to remain as part of the genus *Cervus*, or whether they ought to form an entirely new genus. The zeal and assiduity with which the natural history of the East is now prosecuted cannot leave this point long unsettled.

The species which we have now noticed comprise all the deer of the eastern hemisphere; and if we imagine a straight line drawn from Spain to the Island of Timor, all the countries in the hemisphere which lie to the north-east of this line are inhabited by deer, though partially mixed with antelopes in several of the middle regions, while all to the south-west is the proper country of the antelopes. It is true that deer thrive well in the Mauritius and the Isle of France, but they are imported animals there; and we believe there were no ruminantia in those islands when first discovered.

### III. DEER OF AMERICA.

It only remains now to give a short notice of those species of deer which are found in the American continent, and not in any other part of the world, and we shall take them in order from north to south, though some of them inhabit nearly the same regions. There is, however, some confusion in these species, arising from differences of colour, having been perhaps incautiously made specific.

THE WAPITI—*Cervus strongyloceros*. This species is now well known in Britain, from living specimens being kept in the different zoological gardens; but it is probable that another described species should be referred to this one, namely, the Canadian Stag (*Cervus Canadensis*), of which there are also varieties mentioned. We shall quote Hamilton Smith's description of the Wapiti as being the best, both on

account of the describer, and of the fact (a very important one), of his having seen the animal in its native locality:—"Our wapiti resembles the common stag in nearly all his proportions, but his size is far superior, being at the shoulder from four feet four to four feet eight inches, the superiority of bulk appearing chiefly in the magnitude of the body. The hind is similar to the stag, with inferior proportions; the colour of both in the summer season is fulvous brown on the back; a black spot on each side of the corners of the mouth descends on the under lip, round the eye brown, and down the face darker; the neck also is darker than the body, being mixed with a purplish brown tint on those parts; the limbs are anteriorly dark, and lighter from behind; under the horns long hairs form a sort of dewlap, also darker in colour; the buttocks and tail are pale fawn colour, separated from the brown of the thigh by a dark streak; the tail is short, but varies from two to four inches in length; the suborbital sinus is long, open and naked next the eye; the ears are long, lined with white hair within, and dark coloured externally; inside of the limbs and on the belly the hair is close and buff-coloured.

"The specimens seen in Europe appear somewhat different in their colours from those in America, no doubt in consequence of confinement and grooming. The long hair of the throat, and also much of that on the ridge of the neck and sides, dropping off. This description, derived from comparing several living specimens both in Europe and America, is the summer habit. One individual in his winter fur was of a chocolate brown red, mixed with grey, all over the body; the neck, thickly furnished with long hair, and the woolly soft fur on the forehead, were sepia-brown; the chin pure white, and the buttocks and tail also nearly white.

"Comparing this account with our notes taken on the spot during a winter in America, we find a stag reported to have been brought from the Missouri, but which in reality might have been taken in the northern districts of the state of New York, in the vicinity of the great lakes. He was three years old, four feet six inches high at the shoulder; the nose and legs sepia-black, turning on the neck and back to dun brown; the croup and tail nearly white; the body short and thick like the trunk of an ass; the legs shaped as in a calf, very perpendicular on the buttocks, with appearance of callosities on the knees; the croup somewhat more elevated than the withers; the neck much arched and adorned with some long hair, the full expansion of that part not taking place till the fifth year; the muzzle broad and black; the eyes dark, and the aspect mild; the horns were greatly deformed. On the 17th of February, another sketch was taken of the same animal, his horns were beginning to shoot anew, the cicatrix of the former not quite healed, and their form resembling a flattened globe; his face was covered with woolly hair, extremely thick; on the side of the hinder legs, near the true heel, a gland imbedded in hair secreted an unctuous fluid, which seemed to cause uneasiness, and we were informed that while the horns are expanding the animal frequently rubs the points of the antlers against them; the colour of his fur was a sepia-grey, extremely shaggy. This individual was, according to Mr. Skudder, exactly similar to the specimen shot on Long Island, and might therefore be considered the Canadian variety; and the drawing, compared with

the stuffed specimen in Paris, if it be not the identical animal, closely resembles it.

"The horns of this species acquire a surprising development, expanding with such rapidity that at one period their growth exceeds an inch and a half per day. In the Long Island specimen, of six antlers each measured above three feet in length, and the bur and beam were exceedingly large, but in some individuals they are asserted to exceed six feet. One specimen of which we have a drawing, shows them nearly five feet long. The base and tertian, or brow and royal antlers, are invariably the longest in both the varieties. These seem to be instruments of use, for with them, when a small dead pine, or a bar of a split fence sixteen or eighteen feet long, lies in their way, they will lift and toss it clear over their backs.

"In England, where they have propagated, it appears that some care is required for their preservation, since to an alleged neglect of this kind is ascribed the loss of no less than twelve head of the herd belonging to the king. In Canada they feed on some buds of coniferous trees and grass, and in summer on aquatic plants, which they seek under water while sheltering themselves in that element from the bites of flies. It was in the act of feeding in this manner that we had a view of the Canadian stag. We were in a canoe ascending the Chaudiere, at a point where the river bends suddenly on opening into a small lake. A hunter among us made a warning sign for silence and pointed a-head, but nothing appeared on the surface of the water; the bateau men, however, understood the sign, and grasped their muskets, but with so much precipitation and noise as to alarm the game, which now again put his head above water, and seeing the canoe sprang forward towards the bank with his mouth full of weeds. At this instant he was fired at, but he gained the shore very near us, and dashed with elevated antlers into cover, as was thought, unhurt; he appeared quite black, with large expanded horns, but no further observations could be made. We were then informed that at this period (August) they are often killed while feeding under water, but the canoe must be so placed as to glide with the current and without noise close to them; the game only raising its head to breathe from time to time, takes no notice of an object which appears motionless.

"On the banks of the Missouri they are said to live in small families of ten or twelve individuals, headed by an old male, who is reported to be monogamous; the rest beside the hind being calves and semi-adults. The females are capable of procreating very early, one born in England having produced a calf at eighteen months old. This circumstance militates against the opinion of the Indians respecting their longevity. The males do not bellow, but when they are alarmed or excited send forth a loud piercing whistle, to all appearance from the suborbital slit. They mew their horns in the latter days of February or during March, and require little more than three months to recover them, notwithstanding their enormous size."—*Animal Kingdom*, vol. iv. p. 98, &c.

From the character of its native country, there is little doubt that the wapiti might be added to the ornamental animals of this country; and though it wants the majesty of the stag, the beauty of the roe, and the softness of the fallow deer, yet its size and the grandeur of its apparel would render it a highly interesting variety in the more extensive parks.

NORTH-WESTERN STAG—*Cervus occidentalis*. It is

at least probable that, though the wapiti varies in colour from black to brown, there is another stag, more of a mountaineer, in North America, to the westward of the great central valley; and though this species displays very considerable variety in the extent of its range, it is probable that it occurs in the Canadian mountains, and is the animal described as the Canadian stag, more uniformly red in the colour, and more light in its make than the wapiti. It has been seen at different parts of the west coast, and perhaps ranges along the Stony Mountains as far as California. Its horns are smaller than those of the wapiti; and it has a character somewhat peculiar, namely, that the bezantler, or second on the beam, is longer than the brow antler. The horns are about three feet from burr to tip, very much furrowed and pearly; the brow antler turned downwards over the face, the bezantler forwards or upwards; and the royal, or tip of the horn, consisting of snags from a common centre, as in the stag. There are varieties of colour, but the following is about the average: face dark brown, cheeks and space round the eyes buff, chin and inside of the limbs white, muzzle broad and black, lachrymal sinuses long, ears long, dark outside but inside and margin white, neck, back, flank and hams brown, legs ochre-yellow, tail in some of the varieties long, in others short. Additional information is wanted, however, in order to determine whether there are several species or only one diversified by climate.

**THE VIRGINIAN DEER**—*Cervus Virginianus*. This is what is usually styled the fallow deer of America. It is a very light and handsome species. It stands about three feet three inches in height at the shoulder. The horns are inclined forwards, with their points turned toward each other, so that they are not further apart than the bases. The burr is small, and near it on the inner side of the beam rises a short antler inclining inwards. The first horn is a simple pricket. The second has a forked summit, and then in the fifth year there are two or three snags on the posterior or curved part of the beam. On mature age the upper part of the beam becomes palmated, and the snags become double pointed; the burr also extends, and so does the brow antler, but the horns are subject to very considerable varieties. In summer, the hair of both sexes is of a bright yellow cinnamon colour, which changes to a fine brownish grey during the winter, the hairs of that season being annulated with brown and buff. The belly, inside of the thighs, the internal face of the fore legs, above the knees, and the posterior, inner border of the buttocks, are white; the throat, breast, and under part of the tail, of the same colour; the upper part of the tail dark, and the legs fawn colour; the ears are long and pointed, outside of a brown grey, inside well lined with white hair; the forehead, face, and cheeks, brown with a slight mixture of grey; round the eyes, lips, and chin, fawn colour; the muzzle small and black, no spot on the corner of the mouth, but the winter hair of the belly and under part of tail long and silky, and the bristles on the inside of the hinder joint or tibi-tarsal articulation of a deep rust colour. In this animal the eyes are peculiarly bright, soft, and beautiful. The fawn is of a lively fulvous brown, marked during the first year with numerous white spots. They rut in November and December, when the neck of the buck swells, and gestation lasts near nine months, the females dropping two or even three fawns. The bucks

lose their attire about the same period as the stags of Europe; they bray, but with less noise, and live in herds from the southern confines of the great lakes and the St. Lawrence to the Floridas and westward, in the interior to an immense distance. According to Professor Harlan, this species displays great enmity towards the rattle-snake, which it contrives to crush by leaping, with the fore-feet conjoined, and dropping perpendicularly on the serpent, bounding away again with great lightness, and repeating this attack till the enemy is killed. This species of deer is subject to considerable variations, probably arising from difference of colour, but the specific distinctions are very uniform. Its flesh is very palatable and wholesome, and its skin, which is soft and flexible, is used for many purposes in domestic economy, and is said to resemble that of the chamois more than the skins of any of the common deer of Europe. It is altogether an interesting animal, and forms a very decided feature in the natural history of the districts in which it is found. It is rather more of a lowland animal than the red deer of the Rocky Mountains, but it possesses more elegance of form and more activity of habit than our fallow deer, at the same time its manners are gentle, and there is no doubt that it could be easily domesticated in its native country, and probably in Europe.

**THE MEXICAN DEER**—*Cervus Mexicanus*. This is rather a doubtful species, or at all events the part of America of which it is a native is not very clearly made out, though it is probable that it inhabits the table land, more or less, the whole way from Mexico to the southern extremity of the American continent; and that though it is a mountaineer in the tropical parts, it descends to the plains in Patagonia. The animal itself is little if at all known, but the horns have been in various museums for a considerable time; and as they are peculiar, it may not be amiss to give in substance the description of them, partly from Shaw and partly from the celebrated Grew, by whom the animal is styled the Indian Roebuck. It is probable that the same pair of horns still to be seen in the British Museum are those mentioned by Grew. They are of a bright yellow colour, so irregularly and widely palmated as to cause a suspicion that they once belonged to an unknown species of reindeer, or to a second species of elk. They are nearly seventeen inches long, spreading diagonally from the head and reclining back; there is no burr at the base, only a broad, ascending, tuberculated, and toothed beam. At two inches from the base an antler issues from the anterior part in a vertical direction, flat and ending in two points; about three inches higher the beam, being somewhat prismatic in form, widens, and a broad flat branch throws up four snags in the form of a palm, the foremost plain, the next toothed, the third plain, and the fourth bifurcated; behind these a fifth assumes a still more singular form, it ascends in the same direction with the others, terminating in three processes, and from its external posterior side throws out an horizontal branch which bifurcates again, the inferior being the longest and hanging downwards; this is the right horn; the left, after the basal antler, throws obliquely forwards a flat broad branch dividing into two processes, then vertically one with three external processes, and then a third likewise with three external processes, but these three branches flatten also at the base into a kind of palm obliquely facing the other.

Cuvier describes the horns as strongly curved for-

wards, spreading outwards, and converging towards each other at the extremities; an antler at the anterior face of the beam, pointing vertically, and furnished with strong denticulations; a spiller or antler at the posterior part of the beam, divided into several small branches; these horns flatten into a sort of palm from the second antler, and at their base are deeply grooved and strongly tuberculated. The head which Cuvier describes is that of a very old specimen, which was furnished with a muzzle, but had no canine teeth; and in these and other particulars it appears that the animal bears so strong a resemblance to the Virginian deer, that it is probably only a variety, and that this deer extends throughout all the temperate parts of America, being subject to some variations arising from differences of climate and pasture. The following are descriptions of some of the museum specimens of the horns. In the collection of the late Mr. Brooks there was a pair of a bright golden yellow colour, very robust, rising from the burr with strong pearls, and a small antler in front; behind this, and in contact with it, a second snag, strong, vertical, notched, and grooved; the beam then bends out at an angle, horizontally and laterally, and then curves forward. On the superior edge are three bifurcated snags, two vertical, and the third bent forwards; but what seems to confer a decisive character on these horns is, that beneath these, on the inferior edge of the beam, a sixth heavy snag hangs down perpendicularly, widened and flattened at the base, and evidently much worn by friction, while the animal grazes; this is the character on the left; the right is similar, excepting the extreme points, which appear to have been injured in the development. In the British Museum, there is another similar pair with the worn clavate suspensal snags, but less in proportion. These two specimens seemed to justify the appellation of *Cervus clavatus* for a new species, but they are the companion of several others in the British Museum. There are, however, so many uncertain points in the history of this species, that it must be received with much caution.

**THE LARGE-EARED DEER**—*Cervus macrotis*. This is also an American species, resembling the Virginian and Mexican deer, and also in some respects the wapiti; but according to the descriptions of Harlan and Say, it is different. The upper part is light reddish brown, and the sides and fore part of the nose ash colour; the back intermixed with blackish tipped hairs, which form a distinct line on the neck near the head; tail reddish-cinereous black at the tip; this part is somewhat compressed, and almost naked beneath; the hoofs are shorter and wider than those of the Virginian deer, and more like those of the wapiti; the horns slightly grooved and tuberculated at base with a similar antler, as in the Virginian; the beam less curved forwards, is bifurcated near the summit, again divided, the anterior of the second bifurcation being somewhat longer than the posterior; the ears very long, extend to the principal bifurcation, about half the length of the whole horn; the lateral incisor teeth are larger in proportion to the intermediate than in the Virginian; eyelashes black; lachrymal apertures also larger, and the hair coarser, and undulated, and compressed like that of the wapiti. The species is found in the most remote north-western territories of the United States, and from the context of this description it appears evident that the Guazupuco deer is nearest allied to it, and that the guazuti and the Virginian are clearly of the same group.

**THE LONG-TAILED DEER**—*Cervus macrourus*. This species is described as being larger than the red deer or stag of Europe, darker in colour on the upper part, and having the belly white, the tail, from which it gets its specific name, different from that of most species of deer, is about eighteen inches in length, black on the upper part, but with broad white margins, and carried erect when the animal runs. The

*Cervus macrourus.*

horns are short, and altogether of small size and flattened, but not palmated. This species of deer is described as being very numerous in the dry plains near the banks of the river Kansas in North America. This river is one of the western branches of the Missouri, and drains by its different forks a region of 500 miles in length by more than 100 in breadth.

**THE GUAZUPUCO DEER**—*Cervus paludosus*. This species inhabits the low and swampy regions of South America, and is described by D'Azzara as having horns rather large and cylindrical, terminated by a fork, with an anterior antler some way up the beam, simple or bifurcated, pointing forwards and then vertical; his muzzle is large, figured like that of an ox; the eyes large and full, with a lachrymal fold beneath; the forehead below the horns flat; the ears terminating in a point; the pedicles of the horns are one inch high, and the horns about one foot four inches in length, with never more than five snags; mummæ four, disposed in a quadrangle; the eyelashes black, surrounded with white, which passes along the side of the face, and surrounds the muzzle and the mouth; a black velvety spot in the angle of the lower lip, another shading the nose on the upper; a black triangular one on the nose, and another between the eyes, united by a dark line between them. Inside of the ears, under jaw, and cheek, white; a black spot on the interval of the hoofs of all the feet, ascending to the second joint; a black band passing along the breast, and another on the upper part of the tail. The size of this animal is nearly the same as that of

the European stag, being four feet high at the shoulders, and four inches higher at the crupper. The prevailing colour on the upper part is reddish bay; the tail is of medium length, and the two incisive teeth are larger than the rest. The females are smaller than the bucks, and without the black line on the breast. The fawns are of a uniform dun colour, and without any spots. The hair on the posterior part of the abdomen, and all the way between the hip and the under side of the tail is very long, white for the greater part of its length, but with dark points.

This species is most abundant in the swampy regions of Paraguay, in the centre of South America, and according to the account given by D'Azzara, the season of rutting and also that of shedding the horns are not so determinate as in the deer of the northern hemisphere. This is not to be wondered at, if we consider the character of the country which these animals inhabit. When the rains set in, a very great extent of the surface is laid under water, by which means the deer are dispersed to the margins of the temporary lakes, where they find abundant food; and as the dry season comes on, and the waters subside, they retreat upon the remaining portion of the marsh, which is seldom dried up even in the hottest season. These animals may, therefore, be regarded as enjoying a perpetual summer; and, therefore, as is the case with most animals which enjoy this, their breeding is not confined to one particular season, but is distributed over the whole year. We still know too little of the natural history of South America for being able to decide with precision the geographical situation of this or any other species; but it is probable that the one under consideration is very generally distributed over all the swampy grounds.

**THE GUAZETI DEER**—*Cervus campestris*. This is also a South American species, but inhabits the dry plains rather than the bushy margins of the marshes. This is smaller than the former species, being only about two feet six inches at the shoulder, and two feet eight and a half at the croup; the horns are a foot long, slender, with the beam suberect, a branch anteriorly placed, bent upwards, and posteriorly one or two snags towards the summit; the eyes are large and brown, with a suborbital fold; the ears erect and pointed; the fur smooth and close, is reddish-bay, the hair being reddish-bay at the point, and dull brown at the base; the inferior parts of the body, the under side of the head and tail, which measures six inches, are white, as also the hinder part of the buttocks, and internal face of the thighs, a circle round the eyes and inside of the ears. The hair on the lower part of the abdomen is not so much produced as in the species last described.

It is understood that this species is also very generally distributed over South America, and that it is particularly abundant in Patagonia, the plains and valleys of which are much more perennially green than those of the more tropical parts of America. It resides in the open plains, is remarkably swift; and the male emits, when pursued, a strong smell of onions; which, however, is supposed to result more from feeding on bulbous roots than from any natural quality in the animal, as some specimens which have been kept alive in Europe and fed upon grass, have not emitted the same odour. The horns of this, and indeed of most of the South American species of deer, are, however, subject to so much variation, that there is some difficulty in making them out. The horns of

deer are, indeed, perplexing matters. As we have already said, there are, at least, ten times as many pair of horns as deer; and these pairs are not only all different by nature in different years, but they are liable to accidental differences from hurts or otherwise; and we have further reason to believe that not only difference of climate varies them, but that they are farther varied by differences of seasons. They are seasonal productions, as well as annual plants; and the feathers of birds are, and we know that these are, affected by the character of the season. Farther we know that, in the same species, and even in the same group of deer, the horns are less produced in warm climates than in cold ones; and it follows, by parity of reasoning, that they should be less produced in warm seasons than in cold ones. These and many other circumstances render it very questionable whether the form of the horns ought to be taken as the characteristic of the different species of deer; and it is certainly true that much perplexity has been occasioned by the horns of the less known species, and particularly by shed horns, the owners of which are altogether unknown.

**THE CARIACOU DEER**—*Cervus nemoralis*. This species is considered as a variety of the Virginian deer; though it is understood to inhabit more southerly latitudes, being abundant in the woods of tropical America. In the United States this animal is called the roebuck; and it bears considerable resemblance to the roebuck of the eastern continent. The following is Hamilton Smith's description from specimens, of Virginian origin, which were kept in the hospital gardens at New York: "The horns not more than eight inches long, somewhat vertical, rugous at base, with a small antler not above an inch in height, rising vertically at a short distance up the anterior part of the beam, which at the insertion of the antler, bent back, and then being slightly flattened, turned inwards and forwards in a slightly uncinated bend, throwing off a posterior short snag, which constituted a bifurcation; the buck and does were nearly of the same size and colours; the head rather round, not so prolonged as in Guazeti, and the body longer than the roebuck, about twenty-eight inches high at the shoulders and thirty at the croup; the neck, shoulders, sides, and back, were of a yellowish brown grey; the inferior part of the belly, edge of the buttocks and under tail white; the face darker brown grey; leaving the region round the nose, lips, and chin likewise white, with a black spot on the nose, one at each side of the mouth, on the upper lip, and one at the corner of the lower lip; the space round the orbits and cheeks, dun, with a little whitish favour behind the eye; the ears moderately long and pointed, were brown-grey outside and whitish-grey inside; the eyes full, dark, and soft, with a small suborbital fold beneath; the muzzle small, round, and black; from the knees downward to the fetlock was a dark streak, but the rest of the limbs ochrey; and the tail about four inches long, was dusky above, without any long white hair at the edges.

"While engaged in making the sketch, they were fed with bread, and the buck, jealous of the does sharing the dainty, showed his propensity to leap, for he drove them off by butting them, the head turned sideways, not unlike a goat in play, rising for the purpose high upon his hind legs, and not by running with the head low like the stag. It being in the month of March, their mewing period, he broke one

horn off in this sport, and then made several surprising vertical bounds, but only one drop of blood escaped from his head, and he stole away in a crouching gait under a shed.

"This species is common in all the warmer parts of the American continent which abound in forests. The mahogany-cutters of Belise often meet with it in the woods. It is very lively, but at the same time a most gentle creature, easily tamed, and very familiar in confinement. We are still, however, in want of information respecting it, and also several others of the forest deer of America, the haunts of which are very difficult to explore."

Besides the species which have been enumerated, there is an entire group of deer on the American continent which differ altogether in the form of their horns from the deer of the eastern world, as well as from those species which we have described. They are generally styled *brockets*, from the circumstance of their horns never acquiring any branches, but remaining as single dags, similar to the prickets or first horns of the European stag. The deer of this group are mostly of small size and light make; they are very numerous in some parts of the country; and as the females very much exceed the males in numbers, it has sometimes been alleged there are species of deer in America the males of which have no horns. This is certainly not true, but the horns of this group are insignificant as compared with those of most of the genus. The animals themselves are generally below the middle stature of deer; their nose is pointed, and their muzzle small, consisting of a glandular termination at each side of the nostrils. Their lachrymal sinuses are small, and their colours are generally uniform, the prevailing one being bright reddish brown. They inhabit the thick swampy forests, and are found only in the warmer parts of the continent. Several species are mentioned, but we are in want of precise information respecting them.

**THE PITA BROCKET—*Cervus rufus*.** This is a very lightly formed and handsome animal. The male or buck is styled *Guaru Pita* in Brazil, and it is rather taller than the roebuck of Europe, but more lightly made. The head is very pointed, and the muzzle small, but giving an enlarged appearance at the sides of the nostrils. There is a lachrymal sinus before the eye, and the male has canines; the horns are always simple with a small burr at base, and the pricket about five inches long; the body is of a lively reddish bay, excepting the face and feet, which are red brown; the lips, chin, surface between the under jaws, under part of the tail, and lower abdomen, are white; the throat and internal face of the thighs whitish grey; the tail with the hair is nearly nine inches long, and red bay above; a circle round the eyes is occasionally paler than the rest of the head: the females have the same colours, but are smaller in stature. These animals are found chiefly or entirely on the eastern side of central America, from Honduras to the southern extremity of Brazil, along which line the low country is generally very much wooded, and therefore adapted to their habits. They are gregarious, living in large herds, and are almost the only ruminating animals which are so, and at the same time of a strictly forest character. The males are polygamous; and, as already mentioned, their numbers are few compared with those of the females. They are much preyed upon by the aguars, and also by the larger species of boa.

**THE APARA BROCKET—*Cervus simplicicornis*.** This is a smaller species than the former, standing only about two feet and a half at the shoulder, and being, as is understood, destitute of canine teeth. The profile is remarkably straight, and the horns, which are small and shorter than the ears, are continued in the same line with it. This is a red deer as well as the other, but its colour is brighter, its tail shorter, and furnished on the under side with longer hair. There is a dark ring round each eye, and the mouth is dusky. The specimens of this species which have been examined and described in Europe, have been chiefly brought from Brazil, where they are understood to inhabit more on the open plains than the species last described. They appear to vary very considerably in their colours with age, so that there is some uncertainty about their natural history.

**THE BIRA BROCKET—*Cervus nemorivagus*.** This as its name imports, is a wanderer in the woods. It has sometimes been confounded with the apara, but it is a much smaller and more gentle-looking animal. It is only about a foot and a half high at the shoulder. The horns are straight, smooth, solid, and pointed; rather more than half an inch in diameter, and not exceeding two inches in length. The tip of the ear is rounded, and the lachrymal sinus is very small. General colour on the upper part greyish brown, the hair being brown, with yellowish white points. The lips, the chin, and the middle of the breast are white; the belly, the whole of the fore-legs, with the exception of the outside of the knees, and a space round the eye are buff coloured, the outsides of the hind legs are fawn; the animals are remarkable for the gentleness of their appearance.

The species of which we have given an enumeration comprise at least the greater number of living deer which now inhabit the earth, though it is by no means improbable that in America, both North and South, in the central mountains of Asia, and in the Oriental isles there may be species with which we are not acquainted, and it is possible that some of those which are now described as species may be only accidental varieties; for most species, and particularly those of the warmer climates, are subject to albinism, and also to occasional differences in the forms of the horns.

There is no genus of animals more interesting to the naturalist, in every point of view, than the deer. With the exception of Africa and New Holland, they are found upon every large portion of land on the surface of our globe; and they appear to have existed coeval with some of the races of animals which are now extinct. They have even a fossil history, to which it is of some consequence to attend; and for this purpose we shall briefly mention the principal ones whose remains have been found in the earth.

**FOSSIL DEER.** The most remarkable of these is probably that which has been so frequently met with in the bogs of Ireland, and which has been styled the **IRISH ELK** from the form of its horns, though in the rest of its anatomy it approaches more to the character of a stag. The horns of this fossil species so far resemble those of the elk, that they have large palms which are placed edgewise to the front, and extend wide in a horizontal direction. But they differ in the number and extent of the snags upon the posterior margins of the palms, not being more than eight or ten, while in the mature elk the number is sometimes as many as forty. They differ also in having a brow

antler projecting from the beam of the horn immediately after the burr, which antler is enlarged towards its extremity in all the specimens, and in some of them it is forked. It is understood that these deer in so far resemble the reindeer as that both sexes were furnished with horns, and horns of immense dimensions; the entire length of some of them, including the portion of the cranium between, being not less than ten feet. But though the horns are of this immense size, it does not appear that the animals themselves have been proportionally large; for the bones of the head are not larger than those of a full-grown stag. This species appears to have been very numerous in Ireland, three heads having been found in a single acre; and Molyneux mentions that in less than twenty years thirty had been picked up. These animals have been contemporary with the fossil elephant, which is now extinct as a living inhabitant of Europe; and though they are more abundant in Ireland than anywhere else, they are by no means confined to that island; they have been, however, found in the Isle of Man, and several parts of Great Britain, in France, on the banks of the Nile, and in the valley of the Po; and there is no doubt that proper research would find them in many other parts of Europe; so that we have every reason to conclude that at some very remote period of history, when the state of the country was very different from what it is now, they were very generally and abundantly distributed.

Another fossil species is the fallow-deer of Scania, in Sweden, mentioned in the memoirs of the academy of Stockholm, for 1802. These bones, which were found in a fresh water deposit, are much larger than those of the existing fallow-deer; and yet they differ so much from the horns of the reindeer that they cannot be referred to an accidental variety of that species. They have a single brow antler upon each horn, placed on the beam, between four and five inches above the burr, but small and perfectly simple, and thus totally different from the antlers of reindeer, while the palms of them are vastly larger than those of the horns of fallow-deer.

In the south-west of France there are found the remains of a deer bearing very considerable resemblance to those of the reindeer of the present day, but the animal itself has been considerably smaller, not exceeding the common roebuck. These remains are found in the sands of Etampes, and also in caves, at Breugens in the department of the Lot, at which latter place they are mingled with the bones of the horse, the rhinoceros, and various other animals. The horns stand more erect than those of the reindeer; and though there are several points of resemblance, there is question that the owners of these remains have belonged, if not to a different species, at least to different variety, from the common reindeer. The existence of those remains in the same charnel-house with the bones of the rhinoceros, is a singular and somewhat puzzling point in the natural history of our globe. The reindeer is now found only within the arctic circle; and the rhinoceros only in tropical countries. The fact of their remains being found together, leaves no doubt that they have been co-inhabitants of the temperate parts of Europe. Thus the geologists are put upon the horns of a dilemma; because neither the assumption that Europe was once colder than it is now, nor that it was once warmer, will meet this case, in as much as, so far as our present knowledge extends, we have the remains

of the polar animal and the tropical in the same grave.

In the fresh water formation of calcareous matter at Montabazard, there are found the remains of a species of roebuck, together with two species of lophesodon, and one of mastodon, both of which are now extinct in all parts of the world; so that we know nothing of the kind of country which was adapted to their habits. This fossil species resembles, in many respects, the deer of the Oriental islands, and more especially the deer of Timor, which is the most remote from Europe in its habitat of any with which we are acquainted.

On the deposits near the northern shore of the Mediterranean, there are also various species of deer, some of which resemble the deer of the eastern islands; and, what is singular, their remains are mingled with those of tigers and panthers, which are now natives of warm countries only, as well as with those of the Alpine hare, which are now found living in only the coldest regions of the world. These particulars are highly curious; but they set all our theories at defiance, and render it impossible to say probably what may have been the condition of Europe at some former period of its history.

**DEERINGIA** (R. Brown). A genus of East Indian biennial herbs, belonging to the natural order *Amaranthaceæ*, and nearly related to the *Celosia* or cockscomb.

**DEILEPHILA** (Ochsenheimer). A genus of lepidopterous insects, belonging to the section *Crepuscularia*, and family *Sphingidæ*, or hawk moths, having the wings entire and acute, the spiral tongue rather elongated, and the antennæ short, and gradually but distinctly clubbed in the males. These insects have much the appearance of the insects to which the genus *Sphinx* is restricted by recent authors, but the species are generally smaller, and more robust in appearance, owing to the comparative shortness of the abdomen. Mr. Stephens divides the genus "into two sections, corresponding with their diversities of habit and structure; the larvæ of the second section have the power of elongating or contracting the anterior portions of their body, thence called elephant sphinxes—a term which has been applied to all the species, but improperly." In addition to the external characters of the perfect insects, by which these two sections are distinguished, it may be added, that in the first of them, the caterpillar is completely covered with minute pale spots upon a dark ground, its anterior segments are not capable of being protruded to a considerable distance, and the horn upon the extremity of its back is rough, and the chrysalis is superficially buried; whereas, in the second section, the caterpillars are not minutely spotted, a large eye-like spot appearing on some of the front segments, which possess a very considerable power of protrusion; the horn upon the back is smooth, and the chrysalis enclosed in a cocoon of leaves on the ground. There are eight species of this fine and handsome genus indicated by authors as natives of this country, but two at least of them appear to have been species introduced with imported plants. Of these the *D. celerio*, which feeds upon the vine, has been the subject of much controversy amongst entomologists, amongst whom Mr. Stephens (Brit. Ent. vol. i. p. 128.) who contends against, and a writer in a late number of the Magazine of Natural History, who argues in support of their introduction as real inhabitants of this country, may be especially

noticed. The following observations upon the *Deilephila Euphorbiae*, one of the rarest and most beautiful species of the whole section, will, we are sure, be read with interest. This species is found upon the sand hills of Branton Burrows, near Barnstaple, in Devonshire, in the month of June. On its first appearance the wings are small, clumsy, shapeless appendages, and are more soft and yielding than the lightest silk which undulates with a breath, often remaining for some time stationary in a vertical position upon the stem of the spurge, allowing its wings opportunity to expand and strengthen as they droop behind it. In half an hour the wings are brought forward, and assume their usual position. About half an hour after sunset the *Deilephila* appears on the wing, circling over the various branches of spurge scattered over the surrounding waste, until a mate is found. The eggs are coated with a gummy substance, by which means they are easily attached to the small leaves of the spurge. They hatch in a fortnight, producing small black caterpillars, which shortly afterwards acquire a red head and tail\*. Subsequently they grow very fast, gaining at each moulting additional beauty, by having red dorsal lines, and a great number of minute yellow spots, two lateral ones on each segment, being much larger. When full grown, Mr. Curtis informs us that "they are so conspicuous, that their numbers are reduced by marine birds which feed upon them; they are full grown about the middle of September, when they descend into the sand, and become chrysalides, forming a loose case of earth around them, from which the moths emerge the beginning of the following June. Sometimes, however, they remain in the pupa state two seasons, as many lepidoptera do—a wise provision of nature to prevent any accident from destroying the whole brood. The sand hills where the larvæ are found being of great extent, must have been collected by the winds and storms, to which they are constantly exposed. During the winter the whole soil is frequently removed so as completely to alter the surface of the country. A great number of the pupæ must consequently be destroyed, or buried at a considerable depth below the surface, where probably they lie hid until they are brought to light and life by the influence of the elements."—Brit. Ent., second edition. These circumstances mentioned by Mr. Curtis will enable us, in some degree, to account for the irregularity in the appearance of these insects mentioned to the author of this article by Mr. Raddon, the gentleman by whose exertions the majority of specimens have been obtained, and since published by him in the Entomological Magazine. Since 1819, he has, however, been unable to obtain but a single chrysalis, and the person by whom this was found informed that "the valley in which you desired me to search is completely filled up by the sand, and the whole surface completely altered by the wind." The late Captain Blomer was not able to capture one, although he resided some years upon the spot; and Mr. Cocks, in a letter to Mr. Raddon, says, "it is now ten years since I took the larva, and although I have regularly been in the habit of visiting the locality every year several times, I have never been able to take it since;" although, in 1814, they were so plentiful, that Mr. Raddon found not less than a hundred minute larvæ

upon an armful of spurge, which he had cut at dusk the preceding evening. The rarity of the insect is also greatly increased by the difficulty of rearing it. The late Mr. Fuseli, the Royal Academician, who was a zealous entomologist, was enabled only to obtain one moth from upwards of twenty chrysalides.

The only species abundant in the neighbourhood of London is the *D. Elpenor*, the caterpillar of which feeds upon the ladies' bed-straw in Hackney marshes, Battersea Fields, &c.

DELPHAX (Fabricius), a genus of homopterous insects belonging to the family *Fulgoridae*, having the antennæ inserted in a notch on the lower margin of the eyes, and being about as long as the head, with the first joint shorter than the second. The ocelli are distinct; the head is produced in front into a short pointed and flattened snout, and on its underside it is elongated into a tubular proboscis, directed towards the breast, and which is the instrument by which the insects are enabled to inflict wounds on the leaves and twigs of plants, and to suck up the fluid which flows therefrom.

There are numerous British species belonging to this genus, of small size, found amongst grass and rushes, some of them occasionally do not have their wings developed fully: whereas the same species in certain seasons, and under peculiar circumstances, of which we are unable to ascertain the nature, acquires full-sized wings and wing covers, which latter are, however, not more coriaceous than the former. Mr. Curtis, not aware of this remarkable peculiarity, has formed the subapterous individuals into a distinct genus, under the name of *Criomorphus*.

One species of this genus, the *Delphax saccharivora*, or the *Cane-fly* of the West Indies, is exceedingly injurious in its ravages upon the young and growing sugar-canes in Grenada, and some other of our West Indian possessions. A correspondent of the Magazine of Natural History (vol. vi. p. 407), thus describes the nature of its attacks:—"For these last six months, (back from March 1833), the island of Grenada has been infested with a species of insect that threatens not only great injury to the present crop of sugar-cane, but also to render the labours of the planter entirely abortive for the next crop. I am not aware that any species of insect hitherto noticed has been found so formidable, either in number or destructive qualities, as the cane-fly, which is now propagating, and so rapidly over-running the sugar plantations in this colony. The insect, formed with a snout and beak ending in a bristle, attacks the cane in all stages of its growth, but is more particularly injurious to plants or ratoons when they are young and tender. The under surface of the leaf, and towards the mid-rib, or the course of the larger sap vessels, is selected by the insect for the scene of its operations. There it makes an oblique puncture, resembling that which would result from a lancet introduced in the same direction. Into each of these punctures from five to fifteen eggs are deposited, and each egg is placed transversely with respect to the direction of the fibre of the cane, which serves to overlap them, and thus afford a protection from the many enemies they have amongst the insect race. The aperture is then covered by a very slight substance, resembling that which protects the eggs and young of various species of spider. This substance is always to be observed attached to the posterior part of the body of the insect. When the insect appears on the surface of the leaf after its

first transformation, it seems dull and inactive, and is generally covered with a light floss of the substance already mentioned; but having changed its skin, which it leaves perfect and attached to the leaf, it becomes lively, active, and voracious, and joins in the works of propagation and destruction. There can be no doubt, or at most but little, that the *Aphides* (as the writer erroneously termed the insect to which they, indeed, bear much resemblance in their habits), do not select the sugar-cane merely as a medium for the deposition of their eggs, but that, like millions of other creatures, they also regale themselves with its sweets, and from their numbers, literally to bleed the plant to death.— Like most of its tribe, it produces the substance called honey dew, so much so, that the upper surface of the leaf infected is covered over with it. This substance when dry, becomes black and of a light texture, which being nearly insoluble in water, destroys and interrupts the action of the atmosphere, and aids in the general destruction of the plant."

**DELPHINIUM** (Tournefort). An extensive genus of herbaceous plants, natives of many different parts of the world. Linnæan class and order *Polyandria Trigynia*, and natural order *Ranunculaceæ*. Generic character: calyx corolla-like, of five sepals, the upper one spurred; corolla of one or four petals, the upper one having a posterior horn, the lower sometimes cleft; stamens below the germen; filaments dilated at the base, and short; anthers terminal, oval, two-celled, cells bursting outwardly; styles three or five, and short; stigma emarginate; capsules one, three, or five, having membranous follicles, and with a placenta fixed to the suture; seeds angular and albuminous. From the peculiar form of one of the petals, these plants have received the English name of larkspur, and whether annuals or perennials have always a place in flower gardens. The first are every year raised from seed, the second are increased by dividing the root. The flowers are not only remarkable in form and variety of colours, but also for the intensity of their various tints; the double *D. grandiflorum* is perhaps the deepest blue of any flower we possess.

**DELPHINULA** (Lamarck; *TURBO-DELPHINUS*, Linnæus). This genus of shells, possessing the round aperture of the genus *Turbo*, probably induced Linnæus to consider it of that family; but the united margin of the mouth at once distinguishes it from the turbinates. In many respects it approximates to the genus *Scalaria*, like which it has its whorls sometimes drawn out and detached; but its nacreous substance, in addition to the following distinctions, clearly proves it as not allied to the family. The shell is solid, conical, or sub-discoid, umbilicated, thick, pearly within and under the external coloured coating; the aperture is entire, round, or sometimes trigonal; the whorls of the spire rugged on the outside, and angular on the side of the umbilicus (which is filled with short spines proceeding from the interior side of the whorls not observed by Lamarck), no columella is visible, a calcareous operculum externally tuberculated, which also Lamarck presumed to exist, but probably had not seen; the exterior of the whorls is armed with spines, depressed and singularly palmated at the summits, tubercles, or scabrous striae, which we have said, give it a ragged appearance. Its pearly substance proves it a marine shell, and distinguishes it from the terrestrial genus *Cyclastoma*, though its rounded opening would otherwise entitle it to be ranked with them, in

so far as that distinction holds good. Common as this shell is, it is remarkable that the animal is unknown, but every reason exists to rank this genus in the second class, *Paracephalophora*; second order, *Asiphonobranchiata*; second family, *Cricostoma*. It appears to occupy a natural position in following the genus *Turbo*, and preceding the genus *Turritella*. All the known species inhabit the Indian ocean, and about four are described. There are, however, more known in a fossil state. De France, indeed, enumerates thirty in the formation prior to the chalk stratum.

**DEMETRIAS** (Bonelli), a genus of coleopterous insects, belonging to the section *Pentamera*, family *Carabidæ*, and sub-family *Brachinides*, having the body long and flattened, the tarsi have the penultimate joint bilobed, the chin is obscurely toothed in the centre, and all the palpi have the last joint rather dilated at the base, and pointed at the extremity. There are but few species of this genus which seems to be confined to Europe, two only are British; the type, *Carabus atricapillus* (Linnæus), is of small size, and chiefly found under the bark of trees. It is of a buff colour, with the head and breast black, and thorax reddish.

**DENDROBIUM** (Swartz): One of the most elegant of the epiphytes found in the East Indies and New South Wales. It belongs to the class and order *Gynandria Monandria*, and to the natural order *Orchidææ*. It may be increased by division of the root, and though its natural station be on the stems of trees when wild, it grows well in pots of moor turf. It thrives best in a moist stove, and flowers frequently.

**DENTALIUM** (Linnæus, and modern authors). This very singular genus of molluscs is so generally well known that an elaborate description of them would be superfluous. The shell is a conical testaceous tube, nearly regular, slightly curved, gradually attenuated towards the posterior end, and open at both extremities, resembling an elephant's tusk in miniature, whence its name. Some species are longitudinally ribbed, others with slightly marked annular ribs, formed by the different stages of growth; but the greater portion of these shells are smooth on the exterior. The animal's body is lengthened, subvermiform, enveloped in a fistulous mantle, terminated by a belt or thickened band, pierced in its centre by an orifice with fringed edges; the foot altogether anterior, probosciform, terminated by a conical appendage, received into a species of cup with festooned edges; the head is distinct, oval, a terminal mouth in the middle of a digitated lip, a pair of lateral jaws armed internally with very singularly formed dental processes. The *D. elephantinum* illustrates the species having ribs or striae longitudinally placed; the *D. entalis* those which are nearly smooth, or merely presenting the striae of progressional growth; and to these may be added such species as are narrowed towards their orifice, and the interior doubled by another tube, forming De France's genus *Entalium*. The precise position these molluscs should occupy in the system of malacology cannot at present be finally determined upon, as a further examination of the animal is indispensable. The comprehensive mind of the great Swede suggested their being allied to the *Carinaria* and *Patella*, and modern authors have therefore placed them provisionally in the third sub-class *Paracephalophora hermaphrodita*, first order *Cyrbobranchiata*.

**DENTARIA** (Linnæus). A genus of tuberos

rooted herbs, chiefly natives of Europe. Linnæan class *Tetradynamia*, and natural order *Cruciferae*. These plants are nearly allied to *Cardamine*, but differ in having tooth-like scales at the root. They grow readily in light soil, and are increased by dividing the roots.

**DEODARA.** The specific name of a cedar found in India by Dr. Roxburgh, and introduced into this country in 1822.

**DERMESTIDÆ**, a family of coleopterous insects belonging to the section *Pentamera*, and sub-section *Necrophaga*. This family is of small extent, but comprises several very obnoxious species of beetles. The body is generally oval, rounded at each end and somewhat convex, the antennæ short and clavate, sometimes varying in the sexes; the legs short, with the tarsi five-jointed, and not contractile as in the *Byrrhidae*, the tibia being long and narrow. The genera are *Dermestes*, *Ctesias*, *Megatoma*, *Attagenus*, *Linnichus*, *Trogoderma*, *Globicornis*, and *Anthrenus*. The last named genus, as well as *Aspidiphorus* and *Throscus*, seem to unite this family with the *Byrrhidae* or pill-beetles, with which they are associated by some authors. Of these genera the only one which offers any interesting observations in respect to their economy, is the first, which is the type of the family, and which has received its name from the circumstance that the species of which it is comprised especially attack dried skins, the Greek word *derma* signifying a skin. The mischief which they thus often occasion to very costly materials, has occasioned them to be well-known. The perfect insect, on the contrary, seems only to live for the purpose of continuing its kind, being often found upon flowers, and if it frequents animal matter, it is only in order there to deposit its eggs instead of producing fresh ravages.

It is chiefly in collections of natural history, and in the warehouse of the furrier, that these injuries are committed; in the former they entirely destroy prepared beasts, birds, and insects, and in the latter all kinds of skins, of which they gnaw the surface so as to cause the hair entirely to fall off. They also attack the carcasses of animals exposed in the fields, devouring all the fleshy and tendinous parts, so as to make perfect skeletons of their prey. They also feed upon bacon (whence the name of the typical species *Dermestes lardarius*), feathers, horns, &c. Indeed, it is difficult to guard against their attacks: they elude our search by their small size, and our precautions by their perseverance. Nevertheless, in the great economy of nature, it cannot be denied that these animals tend towards the general good by destroying those kind of putrifying matters, and converting them into a material serviceable for the support of plants, inasmuch as that the air and moisture do not come into action towards the same end so quickly. With the assistance, therefore, of the *Silphæ*, *Histeres*, *Necrophagi*, &c., these insects effect the reduction to their former elements of such portions of carcasses as the flesh-fly has spared, which attacks only the flesh when in a fresh and moist state, and leaves the skin entire.

The *Dermestidæ* seem to prefer dark situations, where they remain inactive, and move only when disturbed, with a trembling kind of gait; they are seldom seen on the surfaces of the substances upon which they feed, but conceal themselves. The larvæ are long, diminishing towards the tail, and terminating in a truncated cone, having, also, two scaly horns on the last segment of the body; they are covered with long

hairs, and have a scaly head armed with powerful toothed jaws. They change their skin several times, according to Gœdart amounting to ten: the exuvæ retain their form so as easily to be mistaken for the larvæ themselves; the back of the head, and several of the front segments exhibiting only a longitudinal slit. The larvæ, when full-grown, seek a convenient retreat, preferring the remnants of the matters upon which they have been feeding. The pupa is white, with the eyes, and several transverse markings of a brownish colour. When touched, it moves the abdomen with considerable force; the perfect insect appears in about a month. The larva of *Dermestes pellio* has a tail nearly as long as the body, composed of long red hairs. The best remedy against the attacks of these insects is the employment of arsenic in the preparation of zoological specimens.

The genus *Dermestes* is distinguished by having the antennæ eleven-jointed, shorter than the thorax, alike in both sexes, with the last joint of the papillary palpi shorter than the maxillæ. There are four or five British species, including the bacon-beetle *D. lardarius* which is of a black colour, with the base of the elytra dirty ashen colour, having three small black spots. It is about a quarter of an inch long, and is very common in houses, &c. *D. murinus* is generally found in moles, hawks, and other carrion hung up in fields or against walls. *D. vulpinus* infests the hides imported by shiploads direct from the Brazils, and so great is the damage which it occasions, that we are informed that the sum of ten thousand pounds has been offered as a reward for its destruction.

**DESMANTHUS** (Willdenow). A genus of aquatic herbs and shrubs found in the East and West Indies. Linnæan class and order *Polygania Monœcia*, and natural order *Leguminosæ*. Generic character: calyx five-toothed; corolla with five distinct or united spatulate petals; inferior flowers apetalous; stamens ten, rarely five; pod evenly lengthened, and full of seeds. This genus was formerly ranked among the *Mimosas*, but separated by Willdenow. The terrestrial species thrive in loam and moor earth, and are propagated by cuttings; the others are grown in water.

**DESMODIUM** (Decandolle). An extensive genus of herbaceous and shrubby plants, natives of America and Asia. They belong to *Diadelphia Decandria*, and to the natural order *Leguminosæ*. Generic character: calyx bracteate, somewhat two-lipped, the upper one cleft, the lower one in three parts; vexillum roundish; keel obtuse; wings short; lomentum jointed, with intervening compressions. These plants are raised from seeds or cuttings, and are kept in stove collections. Among them we find the moving plant of Bengal, formerly called *Heedysarum gyrans*, but now *Desmodium gyrans*. This plant is an annual or at most a biennial, having pinnate leaves, that is, one pair of small opposite leaflets, with an odd one of much larger size. These leaflets have a spontaneous motion when the plant is in a high temperature, say between seventy-five and eighty degrees of Fahrenheit, and at the same time in bright sunshine. The one slowly rises, while the other is depressed, thus alternating in position for hours together. These motions are only noticed when the plant is in the highest vigour, not being observable in very young or in very old plants. It is a phenomenon not yet satisfactorily accounted for by phytologists, but it has all the appearance in its action of that of a hydraulic machine.

**DESMONCUS** (Martial). A genus of South American palms belonging to *Monæcia Polyandria* of Linnæus, and to the natural order *Palmæ*. Generic character: spatha double; flowers sitting. Males—calyx trifid, corolla three-petaled, stamens six. Females—calyx and corolla urceolate; stigmas three, sitting; drupe one-seeded, shell having three pores in the shape of a star at top. This palm thrives in loam and moor earth.

**DEWBERRY** is the vulgar name of the *Rubus cæsius*, a small trailing plant found on barren ground, bearing fruit resembling those of the bramble, only much smaller.

**DIADEMA** (Ranzani). A genus of molluscs united to the genus *Coronula*, of which it forms a subdivision, and is there described.

**DIAMOND**, a mineral body of great value and hardness, first discovered in Asia. The primitive form of this precious stone is the regular octoëdron, each triangular facet of which is sometimes replaced by six secondary triangles, bounded by curved lines; so that the crystal becomes spheroidal, and then presents forty-eight small facets. These two peculiar characters of the diamond are exhibited in the sub-joined figures.

The diamond has been found of a great variety of colours, but those that are decidedly colourless, and those that approach to a rose tint, are most esteemed.

Many stones when rubbed exhibit very distinct electrical effects, and they will attract or repel light bodies which are brought into their neighbourhood. The diamond, when excited, exhibits positive electricity; whereas the other precious stones, if rough, afford negative electricity. In general, however, it does not retain this electricity for any considerable length of time.

The diamond becomes phosphorescent when exposed to the rays of the sun. Many diamonds, however, do not possess this property, although agreeing in colour, form, and transparency, with those which readily become luminous. The continuance of the phosphorescence varies from five or six seconds to a full hour, and this even when the stone has not been exposed more than a few seconds to the rays of the sun. It is phosphorescent under water, as well as in the air. The diamond, when exposed to the blue rays of the prism, becomes phosphorescent; but when exposed to the red rays is not so. The spark from a charged jar produces the same effect as exposure to the sun's rays. Exposure to the light of a wax candle also produces phosphorescence.

Prior to the commencement of the eighteenth century, all the diamonds employed in Europe were imported from the provinces of Golconda and Visapour, in Bengal, and a few from the island of Borneo. They always occur in detached crystals in alluvial

soil; and this circumstance, no doubt, tended to give currency to the fiction of the "Valley of Diamonds" in the Arabian Tales.

Diamonds of any great value in a commercial point of view, were first brought from South America in 1720, and we may now briefly point out the modes of discovering them both in that country and Asia. In Brazil the natives collect the disintegrated sandstone met with at the bottoms of rivers and ravines, and, by washing, separate the clayey matter from the grains of quartz and diamond. The residue is carefully examined for the diamonds it may contain, which are distinguished by their adamantine lustre, and regular forms. In the district of Cuddapah, in Hindostan, the mode of working the diamond mine is as follows:—After all the superincumbent strata, and the large stones in the diamond bed, are removed out of the mine, the small gravel and other constituents of the bed are then carried to a short distance, and put into a cistern, about eight feet square, and three deep. In this situation water is poured upon it, which separates the lighter loamy particles. The gravel and small stones which sink to the bottom, are then thrown into a heap beside the cistern, from which they are conveyed to a smooth plane of about twenty feet square, made of hardened clay. Upon this the whole is thinly spread. The gravel in this position being slightly moistened, six or seven people go over it several times in succession. The first time they pick out only the large stones; the second and subsequent times, the smaller gravel is carefully turned over with the flat of the hand, whilst they as carefully watch for the spark from the diamond, which distinctly marks the situation of this valuable gem.

The locality of the diamond differs, however, in a geological point of view, very considerably in different parts of the world; and, as such, the modes practised by the natives for procuring these precious gems. Thus we find that the diamond mines, as they are called, situated at Banaganpilla, are scarcely any thing more than holes in the surface of the soil. None are deeper than twenty feet, and when a gallery is excavated under the rock, it is so low that the people are obliged to work in it sitting, a mode of operating which an Indian prefers to every other. The solid rock of the hills is an agate, consisting chiefly of a coarse grey hornstone, with rounded pebbles of the same species, or of jasper. At some depth, this rock becomes a ferruginous sandstone, the grains of which are finely cemented together. Through this solid rock they are obliged to make their way before they arrive at the bed in which the diamonds are usually found. They commence at different places as their fancy leads them, with a spot about twenty feet square, which, with iron instruments and steel wedges, they break into slabs and fragments, of from one hundred to five hundred pounds weight. In this way they descend to the diamond bed, which is fifteen or twenty feet under the surface; this bed extends round the whole hill, and is as regular in its thickness and extent as the unproductive beds in the same place: it consists of a conglomerate, composed of siliceous pebbles, quartz, calcedony, and jasper.

The diamond, on account of the splendour of its lustre, its peculiar play of colour, its hardness, and lastly, its rarity, is considered as the most precious substance in the mineral kingdom, and is particularly valued by jewellers. The diamonds purchased by jewellers are generally in grains or crystals, and some-

times coarsely polished. It is also used in the form of a powder by lapidaries, for cutting and engraving upon harder gems; by watchmakers in their jewelled timekeepers; and by glaziers for cutting glass. The diamonds chosen for cutting glass are all crystallised. The faces are curved, and hence the meeting of any two of them presents a curvilinear edge. If the diamond be so placed that the line of the intended cut is a tangent to this edge near its extremity, and if the two surfaces of the diamond laterally adjacent, be equally inclined to the surface of the glass, then the conditions necessary for effecting the cut are complied with. In addition to the cutting and engraving of glass, the diamond has been very advantageously employed in drawing minute lines on the surface of steel, by which all the beautifully variegated tints of the rainbow may be produced.

The largest known diamond is probably that mentioned by Tavernier, originally in the possession of the Great Mogul. Its size is about that of half an hen's egg: it is cut in the rose form, and, when rough, is said to have weighed nine hundred carats. Among the crown jewels of Russia is a magnificent diamond, weighing 195 carats. It is the size of a small pigeon's egg, and was formerly the eye of a Brahminical idol, whence it was purloined by a French soldier; it passed through several hands, and was ultimately purchased by the empress Catherine for a sum equal to about one hundred thousand pounds sterling.

There is only one other diamond which our space will permit us to notice. This is the celebrated "Pitt diamond." It was brought from India by an English gentleman of that name, who sold it to the regent duke of Orleans, by whom it was placed among the crown jewels of France. It weighs rather more than 136 carats, and was purchased for one hundred thousand pounds. This country is not celebrated for the size of the jewels which adorn the regalia of the sovereign; but there are some beautiful models in the British museum of those we have described. For an account of the chemical constituents of the diamond, see the *First Division* of this work.

**DIANCHORA** (Sowerby). A fossil species of shell, the animal of which is consequently unknown. The shell is thin, adherent, regular, symmetrical, equilateral, subauriculated, inequivalve, one valve hollow within, and convex externally; the other flat, articulated by two very distant condyles. It belongs to the order *Palliobranchiata*.

**DIANELLA** (Ker.) A genus of tuberous rooted herbs, indigenous to New Holland. Linnæan class and order, *Hexandria Monogynia*, and natural order *Asphodelææ*. Generic character: corolla rotate, regular, six-parted, and deciduous; stamens below the germen, filaments bent, and thick at the top; anthers linear and erect; style filiform; stigma simple; berry globular, and many-seeded. These plants grow well in sandy loam, and are increased by dividing the roots.

**DIANTHUS** (Linnæus). A very numerous and beautiful tribe of herbs, much esteemed for the elegance of their flowers and for their fine scent. Linnæan class and order, *Decandria Dignia*, and natural order *Caryophyllææ*. The pink, clove, carnation, and sweet-William are all well-known favourites, and met with in every flower-garden; and some of the florist's varieties are highly valued and sold at high prices.

Carnations and pinks receive the greatest attention and care from the florist; the former is the *Dianthus Caryophyllus* of botanists, and the improved variety

of the clove of florists. It ranks as the chief of stage flowers, as it combines elegance of form with variety and delicacy of colours, and to these is added the most delightful fragrance. To have flowers in the greatest perfection, new plants must be raised every year; not but that old plants will continue to yield flowers for several years; but these being those of branches, are never so large or so fine as such as are produced on the central stem of a maiden plant. Young plants are obtained by layering the lower branches of the last year's layers; and though these be only the points of the secondary shoots, yet when separated from the parent stock, they become, as independent beings, ten times more vigorous and amplified than if they remained on their original roots.

The cultivation of choice carnations forms a principal part of the florist's business. They are usually named, and the superior sorts, especially if they are new, sell at high prices. New varieties are obtained from seed; but very fine stage or prize-flowers occur but as one in a thousand inferiors. A seedling of promising merit, may, by judicious culture, be advanced to rank with the best; and it is by accident, and such means, that our present stock of fine carnations has been in course of time obtained.

The standard choice sorts are perpetuated by annual layering. This is performed about the time or soon after the plants are in flower; but if layered before, or as soon as the shoots are ready, the better. If cultivated as stage flowers, they are kept in pots, and of a pretty large size, in order that their branches may be conveniently layered. If cultivated in beds, there they are also layered; because there must be an annual supply of young plants as well for beds as for pots.

Carnations are layered like other plants; the lower branches, which would not flower till the following year (supposing them to be left on the parent stool), are chosen; an incision is made with a keen pen-knife entered a little below the third or fourth joint from the top, and passed up the middle of the shoot as far as the next joint. This separated piece is called the tongue, and when the little piece below the bottom joint is cut square off, it is ready to be fixed in the soil. In layering, a little fresh compost is usually laid round the plant to receive the layers. In this, little furrows are made, and in which that part of the layer between the tongue and the root is bent down and firmly fixed by a little hooked stick. The layer is then covered with about three-quarters of an inch of the compost; and at the same time the point of the layer is gently raised upright, taking care that the tongue be kept apart from the place whence it was cut, and pressing the soil pretty closely over, and around the point of the layer to keep it in place.

New roots are soon produced at the lower end of the tongue, and towards the end of September are fit to be taken from the stools and planted in beds or pots previously prepared for them.

Some florists are very curious in forming their carnation compost; mixing together many different substances, as loam, sand, leaf-mould, and rotten dung of various kinds. Such a compost may be very suitable, but many successful cultivators use only the freshest maiden loam, made sufficiently rich and porous by a third part of thoroughly decomposed stable or old hot-bed dung. In this, carnations, whether in pots or in beds, thrive and flower in the highest perfection, provided they receive all other necessary treatment.

The management of carnations consists not only in placing the layers in suitable soil, but in taking care that if potted, the pots be well drained, so that water may not stagnate within, which would materially check the growth and spoil the beauty of the flowers. Water must be always supplied moderately, and without excess of either moisture or dryness. The layers when taken off the stools are first placed in small-sized pots, and usually shifted twice into larger, before they are brought to flower. The most perfect cleanliness, keeping free from weeds, and defending against snails, slugs, ear-wigs, and wood-lice, are all indispensable, through the whole course of their growth. When the stems are advancing to flower they are often attacked by the green-fly or aphides; these must be banished by tobacco-smoke, or some other means not hurtful to the plants. Props must also be timely fixed to tie the stems to, as they advance in height; and as several flower-pods will appear on the same stem, all but the topmost, or the two topmost, should be cut off; this is for the purpose of encouraging the principal flowers to bloom in greater beauty and amplitude.

In order to assist the flowers to expand regularly and handsomely, florists exercise certain manipulations which are exclusively their own; these are called *hooping* and *carding*. The calyx or flower-cup is liable to burst irregularly, that is, it will be rent lower down on one side than on the other; to prevent this, two expedients are practised: the first is causing the divisions of the flower-cup to open equally by assisting the backward ones with the point of a penknife; and the second is by *hooping*, that is, by fixing a band of matting or soft string round the middle of the flower-pod, by which means the divisions of the calyx are made to burst regularly. These precautions regulate the bursting of the calyx; and in order that the corolla, or coloured petals of the flower may be expanded laterally and symmetrically, circular cards (having a hole in the centre to embrace the calyx) are fitted on immediately behind the spreading petals of the corolla, the card acting as a support to the petals, which naturally incline to fall back. By these means the petals are exhibited in a plane; besides which every tint and form are seen to the best advantage, and when so dressed up by the skill of the professional florist, are certainly objects of great beauty.

These practices are only followed by flower-fanciers who exhibit their flowers at shows for prizes, and at which there is sometimes the most intense and lively competition.

Pinks receive nearly the same treatment as carnations, only instead of being layered, they are propagated by cuttings, technically called "*pipings*." This is usually performed in June or July, or as soon as the best sorts can be ascertained by view of their flowers. See article *Pink*.

The annual sorts of *Dianthus* are raised from seed; and all the other species and varieties may be propagated by layers or cuttings without difficulty.

**DIAPERIDÆ.** A family of coleopterous insects belonging to the section *Heteromera*, and sub-section *Toxicornes* of Latreille; the head is disengaged from the anterior margin of the thorax, which is either square or cylindric, and, as well as the elytra, not dilated into a flattened margin, as in the *Cossyphidæ*. Latreille places in this family the *Phaleriæ*, and some other genera which appear to belong to the family *Tenebrionidæ*, in which family, indeed, the whole of

the present group is arranged by Mr. Stephens, whilst Mr. Curtis considers the *Diaperidæ* as nearly allied to the *Helopidæ*; the perfoliated or serrated antennæ, which are never moniliform, will well distinguish them. The other genera are *Uloa*, *Diaperis*, *Hypophæus*, *Trachyscelis*, *Cozelus*, and *Eledona* (*Boletophagus*, Fabricius). The family is not extensive, as regards the number of species, some of which are elegantly marked and coloured, in which respect they certainly approach the *Helopidæ*. The species are of small size, and are, for the most part, found in fungi, Boleti, under the bark of decaying trees, &c. The typical genus *Diaperis*, Geoffroy, is distinguished by the antennæ, of which the three basal joints are slender, the remainder broad, transverse, and distant from each other. The type of the genus is the *Chrysomela boleti* of Linnæus, of a rounded form, and black colour, having the base and extremity of the elytra, as well as a central interrupted fascia, orange-coloured.

**DIAPHORA** (Stephens; *CYCNTA*, Hübner. Steph.) A genus of lepidopterous insects, belonging to the family *Arctiidae*, and consisting of a single species, the *Bombyx mendica* of Linnæus, having the wings short, and clothed with but few scales, whence the English name of the moth (spotted muslin); the palpi have the terminal joint slender and obtuse. The name of the genus alludes to the great diversity between the sexes of this moth, the male being of an ashy brown colour, whereas the female is white, with black spots. It is about an inch and a half in expanse. We have already on several occasions noticed the occasional periodical delay which takes place in the development of insects, and this moth offers a still more curious instance, it being recorded by Marshall, that out of thirty-six caterpillars hatched from a brood of eggs, all of which fed together and spun their cocoons at the same period, twelve only appeared at the usual season; twelve more were produced the following year, and the remaining twelve the third season; as perfect and healthy as those produced at the first. The moth is not uncommon in marshy districts near London, appearing at the middle of May.

**DIAPRIA** (Jurine). A genus of minute hymenopterous insects belonging to the family *Proctotrupidæ*, and distinguished by the beautiful antennæ of the males, which have the joints globular and connected together by slender articulations and ornamented with whorls of hairs. They are found in grass, upon trees, &c., and are supposed to be parasitical upon other insects.

**DIAZOMA** (Savigny). A genus of molluscs united to the genus *Botryllus*.

**DICERAS** (Lamarck). A fossil genus of molluscs, approximating to the genus *Chama*, from which, however, it differs by being regular, equivalve, never attached by the lower valve, and the distinct character of the hinge.

**DICERATA.** The second family of the second order *Polybranchiata*. Second class *Paracephalophora*. The general characters of these molluscs is their possessing two tentacular retractile appendages placed on the upper part of the body in a kind of sheath, situated at their base; a membranous wing or sail, more or less extended above the mouth, the organs of respiration in the form of little branches, externally placed.

**DICERMA** (Decandolle). A genus of undershrubs, indigenous to India. Elegant diadelphous plants, formerly called *Zornia* and *Hedysarum*, by

Linnæus, but since new named as above. They are easy of management and propagation, like other stove plants.

**DICHELESTIUM** (Hermann). A curious genus of parasitic, entomostracous, crustaceous animals, belonging to the order *Pæcilopoda*, and section *Siphonostoma*, having the body long and narrow, composed of seven segments, the first of which is larger than the rest, with a pair of slender filiform antennæ, a pair of short didactyle claws, a tubular sucker, three kinds of feelers, four short legs for prehension, terminated by several toothed hooks; the second and third segments are lunate in form and furnished with very short legs; the sixth segment is long and somewhat cylindric, and the last small and oval. The animal of which this genus is composed is rather more than half an inch long, and insinuates itself into the flesh and the gills of the sturgeon, as many as a dozen having been found upon one fish. Of this number three of the specimens were one-third smaller than the others, with the body curved: one of them lived three days when removed from the fish. They are enabled to retain firm hold of their prey by means of their strong frontal pincers.

**DICHLAMYDÆ**, a subdivision of dicotyledonous plants, including those which have a double floral covering, or both a calyx and corolla. The greater part of the handsome flowering trees and shrubs are found in this division.

**DICHONDRA** (Forster). A genus of evergreen creepers, natives of the West Indies. Linnæan class and order, *Pentandria Digynia*, and natural order *Convolvulaceæ*. This succeeds well with ordinary stove management, and may be increased by cuttings.

**DICKSONIA** (Heretier). A genus of exotic ferns, so named in honour of James Dickson, a British cryptogamist of great abilities and unwearied industry. It belongs to the order *Filices*, and one of the species is a tree fern from St. Helena.

**DICLIPTERA** (Vahl). A genus of tropical plants, mostly under shrubs, belonging to the class *Diandria*, and to the natural order *Acanthaceæ*. Generic character: calyx bracteate in four or five divisions; corolla two-lipped, the lowest nearly entire; anthers two-celled; capsule roundish, nearly one-celled, dissepiment ultimately free, to which the seeds are attached. This genus is nearly allied to *Justicia*, but differs in the structure of the capsule. It thrives in rich light soil, and is propagated by cuttings.

**DICLYTRA** (Borckhausen). A diadelphous genus of plants found in the north of Asia and America, and belonging to the natural order *Fumariaceæ*. Some of the species were at first called *Fumaria*, and others *Corydalis*; but these, together with five others, are now known by the name first above given.

**DICOTYLEDONES**, or **EXOGENÆ**, a division of vascular, flowering, or phænogamic plants, in which the vessels are arranged in concentric layers, the youngest of which are external, and the cotyledons of the embryo are opposite or verticillate: the dicotyledonous plants have a more or less conical trunk, consisting of bark, wood, and pith; the wood being contained between the other two. The thickness of the trunk is increased by an addition of new matter between the wood and bark. They have reticulated leaves which are distinctly articulated with the stem. The veins of the leaves are much branched; the flowers have generally a double perianth (dichla-

mydeous), and frequently exhibit a quinary division. The embryo is furnished with two cotyledons (hence the term dicotyledonous), which after germination, frequently assume the appearance of leaves. By these characters the plants of this division are distinguished from those of the monocotyledonous class.

**DICTAMNUS** (Linnæus). Hardy ornamental herbaceous plants, said to be natives of Crete, but long cultivated in this country under the name of *Frarinella*. The flowers are decandrous, and accord in character with those of the natural order *Rutaceæ*. There are two species, both of which grow any where, and are raised from seeds. Dictamnus is also a specific name of an origanum (marjoram), commonly called Dittany of Crete.

**DICTYOPTERA** (Leach). The family of the cock-roaches (*Blattidæ*), on account of the flattened oval form of the body, the five-jointed tarsi, and several other less important characters, was considered by Dr. Leach as sufficiently distinguished from the other orthopterous insects to warrant its separation as a distinct order, to which he applied this name. His arrangement has not, however, been followed in this respect. See **BLATTA**.

**DIDELPHUS**—Opossum. A genus of marsupial, or pouched animals, inhabiting the American continent, and the first animals of this singular order which are known to naturalists. Their generic characters are ten incisive teeth in the upper jaw, and eight in the under, the intermediate ones in the upper jaw being longer than the rest; the three front grinders compressed, and the last four tuberculated; those above triangular, but the under ones oblong, and two canines in each jaw, making in all fifty teeth, which is a greater number than is possessed by quadrupeds of any other genus. Their gape is wide, and the appearance of the mouth ragged; but their bite is feeble, compared with the size of their biting apparatus. Their tongues are beset with horny tubercles, like those on the tongue of a cat; and their tail is in part naked on the under side, and prehensile. Their ears are large and naked, and their aspect is altogether very peculiar. Their hind feet have the thumb or fifth toe long, and capable of acting in opposition to the other four, so as to lay hold like a hand. The four toes which act together on the hind feet are furnished with nails; and when not used in grasping, the nailless one is turned to the rear, like the hind toe of a bird. Their legs are short in proportion to the size of their bodies; they plant their feet upon the round pad of the sole when they walk, and their rate of motion on the ground is but slow. In trees, however, which the greater number of them chiefly inhabit, they have much power of themselves, and climb and hold on with much address. Their eyes have the irides yellow, and the pupils are vertical, like those of the fox. It has been said of them that they have a gape like a pike, the ears of a bat, the feet of an ape, and the tail of a serpent; and, certainly, taking their characters all in all, they differ very much from the placental mammalia. The difference extends not only to the form of the body, and the structure of those parts upon which the classification is founded, but it extends to the very covering, the hair of the opossum being unlike that of most other animals. It is neither sleek nor frizzled; and it has more resemblance to whalebone than to common hair, and on the naked parts there are sometimes scales. This uncouth sort of covering the semi-

transparent ears, which appear reddish when seen against the light, the yellow sinister eyes, the short legs, and the singularly formed feet, give these animals a repulsive appearance, which is in no wise diminished by the very fetid and offensive odour which they give out. The different species vary considerably in their habits; but they may be generally described as nocturnal animals, the principal part of which inhabit trees, in the holes of which they lodge; and they prey upon birds, lizards, and other small animals. Some of them also haunt the margins of the waters and feed upon shelled mollusca and crustacea.

All the species have the general characters of marsupial animals, the most remarkable of which in the skeleton are the two marsupial bones attached to the pubis, which support the pouch. The whole of the opossums have not, however, a distinct and produced pouch, into which the young can be received, and, therefore, there are some distinctions between them in the economy of their gestation, which can be more fully explained when we come to mention the species.

We shall have occasion to notice the general subject when we come to the article MARSUPIATA; and, therefore, we shall in the mean time confine ourselves chiefly to the popular description of the species.

They are, as we have said, all nocturnal animals; and they are all carnivorous; but they do not possess the same degree of power and energy as the carnivorous animals, properly so called; and they are remarkable for stupidity, or at all events they do not display the same cunning as the fox, though their eyes resemble those of that animal. The habit is different, however; for the opossums, generally speaking, seek their prey in trees, whereas the fox is an animal which, though fond of brakes and other cover, is incapable of climbing. The form of their hind feet enables them to lay hold of a branch, and retain that hold, while they have perfect a command of the head and anterior extremities for other purposes. Thus they can make use of the crooked claws with which their fore-feet are armed, to help them in the capture of their prey. At settlements near the woods, where they are plentiful, these animals are sometimes apt to play the weasel in poultry yards; and, like that animal, they suck the blood of their victims.

It is not a little singular that marsupial animals should be found in two zones of the earth, which lie nearly on opposite meridians, the centre of the one about 120° east, and the other about 60° west of the meridian of London; and that in all the districts between them there should be no animal of this character, or even approaching to it. What stage of the geological duration of countries may answer to animals of this singular order; it is not easy to say; for, though we admit that a few specimens have been found fossil in our own latitudes, it is impossible for us thence to conclude that the animals belong either to an early or a late stage of the country; for we have them in the rich woods of South America, and in the comparatively barren extent of New Holland, while there are none in Southern Africa, which is intermediate between these, and partakes of the characters of both.

We shall now briefly enumerate the species; and first those in which the female is furnished with a distinct abdominal pouch for the reception of her young during a portion of the period of gestation, and as a place of safety occasionally till they are able to shift

for themselves. Of these there are three tolerably well established.

THE VIRGINIAN OPOSSUM—*Didelphus Virginiana*. This species is by far the best known, at least to the people of this country, from its abundance in the southern parts of the United States. But as it is very generally distributed over America as far as the borders of Patagonia, or at all events to the margins of the Pampas, the name Virginian is by no means descriptive of it: indeed there is nothing tends more to confuse the nomenclature of natural history, than the naming of natural productions, whether animal or vegetable, after places, or after individuals of the human race. The first method ties the production down to the place named; and though there may be no great harm in naming a particular breed of cattle, sheep, or pigs, after the place which is most famed for their production, yet in cases like the one under notice, it is very absurd,—the Virginian opossum being found over a range in latitude of certainly not less than five thousand miles, while the individuals are far more numerous in South America than in North, if the whole surface of each be taken.

The usual size of the opossum is the same as that of a cat; its covering consists of a mixture of black and white hairs, with the ears having the one part black and the other white. The head often entirely white. It is very generally distributed, inhabits the woods, is not timid in the vicinity of settled places, prowls about in the night, killing poultry, sucking eggs, and committing other little depredations; but we need hardly add that, to man, it is quite harmless. The young, which are often as many as seven in number, are exceedingly light and small, at the time of their birth, that is, the time of their first birth, when transferred from the internal uterus to the pouch. The gestation in the uterus lasts twenty-six days, at the end of which the young have no vestiges of eyes or of ears, and are, indeed, little else than small lumps of gelatinous matter. They do not open their eyes till about the fiftieth day; but they readily find out the teats in the pouch, and attaching themselves to these, they increase in size. They remain in the pouch, or at least resort to it occasionally as a place of safety, until they are grown to about the size of rats.

The Virginian opossum, extending as it does over so vast a range in latitude, is subject to much variation of colour. There is also considerable difference between the appearance of the young ones and those which have arrived at perfect maturity. The body of the young animal is generally of a yellowish-grey, mixed with some hairs entirely white, and others entirely black; the last of which are most abundant along the back, and give that part of the animal the appearance of being marked with a dorsal line. A band of a similar colour descends from each side of the neck to the fore-legs; these legs and also the hind ones are covered with black hairs, and the tail is covered with scales, with a few short and weak hairs thinly interspersed. The hands, that is the prehensile parts of the hind feet, the ears, and the point of the muzzle are naked. The skin on the soles of the feet is violet black; but the toes and nails are flesh-coloured. The whiskers, which appear to be used as instruments of touch, as is the case with all mammalia which seek their prey by night; and it is presumed also, that the toes, which have a very delicate covering, are highly sensitive. The eyes are small, without any external lids, and are remarkable for their convexity and consequent projection beyond their

sockets; and from this peculiar structure of the eye, it is probable that the animal sees only at short distances, but that its vision there is quite microscopic.

Virginian opossum.

From the structure of the nose it is presumed that the sense of smell is very acute; but it cannot be very delicate in our way of estimating; for in that case the animal would be perfectly intolerable to itself, the odour which it emits when disturbed or threatened being described as one of the most offensive in nature. But there is no subject upon which we are more in the dark, and more likely to remain so, than that of the senses of animals. We know the operations of our own senses very imperfectly; and in the case of smelling in particular, we are unable to say what is the specific difference of affection in our organs, which makes us turn with feelings of pleasure to the odour of roses or of new hay, and shun with pain and aversion that of such an animal as the opossum. Now, if we know little of these matters in our own case, where the pleasure is mental, and, whether we understand its foundation or not, a result of reason and experience, and given us as one of the means by which we are to understand the properties of things, and apply them to our uses in the most pleasing, and at the same time, in the most economical manner for the good of the whole;—if we are thus ignorant in our own case, where we have something of more importance than the mere animal sensation to guide us, what can we know in the cases of the other animals? and not knowing, how can we reason?

Still, this is a subject upon which it is exceedingly difficult for any body to refrain from speculating, and it is nearly, if not altogether, as impossible for any body to be right in such speculations. We are, however, thus far certain, that no animal can feel what we call mental pleasure from sensation, apart from the office which that sensation may supply in the mere economy of the animal. Thus, for instance, there is no material eye, except that of man, which can see beauty in form or in colour, neither is there any nostril, save his, which can scent fragrance, and derive from it those emotions of delight, which we never fail to experience when the healthful breezes come to us

sporting over beds of flowers. But, if we cannot suppose animals have the pleasures of sense, which are mental or supplemental to the mere excitement of the bodily organs, we cannot suppose that they should have the opposite feeling of deformity to the eye, and ungrateful odour to the nose. Upon this principle we can readily perceive that, offensive as the smell of the opossum is to our feelings, it may itself be altogether insensible to that odour which instinct teaches it to give out, probably as its chief means of defence.

In many parts of South America the opossum is so abundant, that it prowls about in the villages, and even in the towns. D'Azzara mentions that they are frequently found lying dead in the villages near the shores of La Plata, and even in the streets of Monte Video. He was the first to get a correct account of the marsupial apparatus of the female, which we shall give in nearly his own words. "The female has the whole length of the belly cleft or slit, and appearing like a person's waistcoat buttoned only at the top and bottom. This cavity the animal has the power of firmly closing. Within it are thirteen teats, extremely small, one in the centre, and the rest ranged round it."

Before the female comes to maturity, this marsupial apparatus is but little developed, there being only a slight fold of skin on each side the abdomen. After the young are weaned, the marsupium also collapses, and it is gradually reproduced as the time approaches when it is to receive a new litter. There seems indeed to be, so to speak, an alternation of the two systems of gestation in these curious females. The uterus is the place where impregnation is effected, and where the germ is developed, at least in its early stage; but as this takes place when they are in a much more rudimental state than any young animals which pass at once from the uterus to an external mammary system, there is a degree of excitement required in the marsupial apparatus which is not needed in the case of those animals which produce their young comparatively mature, and capable of taking the teat at intervals as nature requires. The perfect marsupial animals, or those which have the internal and external periods of gestation pretty nearly of the same length, remain on the teat, like any moveable excrescence, until they are completely developed; and it has been ascertained, that in some of the species at least, there is a sort of umbilical cord which connects the young with a sort of placental substance in the body of the teat, until it acquires its form and some of its functions as an animal, at which time it breaks this second connection with the mother, or is born a second time, now an independent animal, capable of drawing milk from the teat, and in due time of finding its food. But this second gestation in the marsupium is clearly as essential to the perfect development of the animal as the first gestation in the internal uterus; and we can no more imagine an opossum to come to maturity, if it enjoys only the first, and has not its full time in the second, than we can imagine the untimely birth of any other animal to become mature.

This is a most extraordinary piece of nature's economy, and a part, the design of which we are unable, in the present state of our knowledge, to comprehend, and yet it is one which very powerfully and pressingly tempts us onward to inquire.

Now, we perceive that this double gestation, by means of the internal uterus and the abdominal pouch, stands as it were midway between the single internal

gestation of the ordinary mammalia and the internal elaboration of the egg, and external, and we may say unconnected evolution of the chick, by the process of incubation, in birds. The common mammalia require the internal warmth, protection, and action of the mother, with perfect exclusion of the atmosphere from contact with the body during the whole time that the fœtus is coming into form. The bird requires that the egg shall be matured in the ovary and oviduct of the mother; but when this is once accomplished, the connection, that is, the material connection, as conveying substance from the one to the other, is cut off for ever as between the parent bird and the future chick, which is still a formless embryo in the egg; so that the egg may be hatched, for the evolution of all the necessary membranes and vessels, and the chick itself may be brought forward by the heat of another bird, or by any heat, if properly applied. We have therefore a second life, as it were, in the young bird, in the action of which the parent bird has no necessary concern; and, if placed in favourable circumstances, by the exclusion of atmospheric air and the light, we know not for what length of time the egg of a bird might not be preserved with the principle of life within it, ready to be called into action by the necessary stimuli, and capable of restoring the species again to the world, even though, by any catastrophe, all the ancestors of the egg were swept away. It is not so, however, with mammalia, for they would necessarily perish, not only with the individual, but with any circumstance which might affect the internal health of the mother during the period of gestation.

The marsupial animal is intermediate between these; and we may reasonably suppose, that as the second stage of its progress in organisation takes place externally of the mother, and partially exposed to the atmosphere, we may very naturally conclude that this marsupial fœtus, being in less intimate connexion with the system of its mother than an uterine one, must not be so subject to suffer with the sufferings of her system, but that the mother, with the young in the marsupium, must be able to undergo greater privations, and bear greater hardships, than the uterine mother. We know, also, from the observed fact, that a marsupial mother can bring forward not only two, but perhaps three successions of progeny at the same time: There have been found some in the internal matrix, and some others in the marsupium, so differing in size and development, that they must have been the products of separate impregnations. No doubt, we have cases of superfœtation among uterine animals, as, for instance, in the common hare, but the authenticated ones are very few in number; they are probably all referrible to the category of "monstrosities of habit" which take place in animals, as well as monstrosities of form; and, at all events, they form the exception, and the rare exception—not the rule. During marsupial gestation, on the other hand, reimpregnation is so common, as to be the rule, and not the exception; and it accords with the economy of nature that such should be the case. There is, therefore, evidently an absolvment of the system of the marsupial female from what would be called the labour of maturing the succession, at that very time when this labour falls most heavily upon the uterine mother, and renders her more helpless than at any other state of her mature and undecayed existence.

Hence we see that the marsupial animal is fitted for contending with, and triumphing over, hardships

which the common mammalia could not so well endure; and if, having found this power in the animals, we can discover a corresponding occupation for this power in the countries where such animals are found, or in the situations in which they have to preserve their lives and find their livings, then we are in possession of two elements which will enable us to approach at least to the outworks of this the most impregnable point in the whole physiology of animated nature.

Now, it will not fail to occur to every reader, who has the slightest general acquaintance with the economy and relative distribution of productions on the surface of our earth, that the three grand localities, or, strictly speaking, the two only, for New Holland and the Oriental Isles, and south-eastern peninsula of Asia, may be considered as one great district, which is cut off from much migration of land-animals by the intervening seas, but over which birds migrate with the changing monsoons in numbers, which to us, lying as we do at the outskirts even of the migration of Europe, Western Asia, and Africa, would be perfectly incredible, if we did not know the fact from the most undoubted authority; it will readily be seen, that this tract, and also the eastern side of America, which, from the great cordillera of the Andes running near the west coast, comprises by far the greater part of the continent, are countries beyond all others stocked with tree birds; and not only this, but that, generally speaking, quadrupeds, with the exception of these animals, are few, and of only trifling dimensions. Australia, which, from the dryness of its surface at one season, and the torrents in which rain falls at others, may be regarded as having the extreme character of this species of country; and the quadrupeds there, with a few very trifling exceptions, are all marsupial, whether they feed on animal matter or on vegetable, and whether their chief prey be sought on trees or on the ground. In South America the character is less extreme, but still it is not less of a tree-bird country than any part of the East, at least in those regions which are covered, as much of it is covered, with extensive and luxuriant forests. The changes of season are very great in all those countries; and therefore, the labour which the animals have in finding their food is sufficient to account for the absolvment of the females from that portion of systematic labour in bringing their young to maturity which we have seen that they enjoy. This is not the place for entering fully into the question; but as all the principal genera of marsupial animals occur in the order of the alphabet before the general article MARSUPIATA, we shall collect the leading points of the evidence in the particular articles, which will enable us to sum them up more briefly, and with a better chance of being understood, than if we brought a question so curious and so complicated into one article. We shall therefore now resume our notices of the species *Didelphus*.

THE CRAB-EATING OPOSSUM—*Didelphus Cancrivora*. This animal has more the figure of a rat than the former. Its forehead is nearly straight, and its muzzle much pointed. The general colour of the head is white, with a few scattered bristly hairs, as whiskers, on the upper lip and on the posterior part of the cheek, and one or two over each eye; the eyes and ears are also black, which form a striking contrast with the general white colour of the face and head. The ground colour on the neck, the back, and sides, is yellowish, sprinkled or grizzled with black and

white, the black hairs being shorter than the yellowish, and the white ones longer, but with a portion of black at the points. These long hairs form a sort of line along the back, and when the animal is excited, it has the power of erecting them. The legs and feet are wholly black, with the exception of the last joint and the claws, which are white; the tail, which is covered with scales and very short hair, is black at the base, and white for more than two-thirds of its length toward the tip. It is tapering to the end, and prehensile.

Crab-eating opossum

This animal is remarkably low upon the legs. Its whole length is about thirteen inches, exclusive of the tail, and its height not above six inches, while, from its applying the whole length of the hind feet to the ground, and having the fore ones short and crooked, it is much lower at the shoulders and the crupper than at the middle of the back. It has been observed principally on the warm shores of South America, where it resides in the holes of the rocks above water, and seeks its food chiefly off crabs and other crustaceous animals. Its hind feet are well adapted for grasping, like hands, and its fore paws, which have sharpened crooked claws, and the toes much divided, are also good prehensile instruments; but, in addition to these, it is said to render its tail available, by thrusting it into the holes which the crabs inhabit, and drawing them forth to their destruction.

**THE FOUR-EYED OPOSSUM**—*Didelphus Opossum*, is the only other known species which has the marsupium fully developed. Like the former, it is an inhabitant of the warmer shores of South America, but it is a more inland animal, and its food is different. It is rather smaller than either of the former, being about a foot in length, with the tail about one foot two inches. Its head is pointed, the whole of the profile forming a straight line. The ears are large, round in their form, and very thin in their substance.

The prevailing colour in the upper part is reddish brown, mixed with grey on the back, but purer on the head. On this dark colour there are placed two circular spots of white in front of the ears, and it is from these two spots that the animal gets the name of four-eyed, just as some breeds of dogs in this country get the same appellation from two brown spots on a black ground immediately over the eyes. The under part is dull white; a small portion at the root of the tail is covered with the same hair as the upper part of the animal, while the remaining part of that organ is nearly naked and scaly. The female has six or seven teats in the pouch, and in these animals there is a different arrangement from the teats of common mammalia; in them they are arranged in pairs right and left, while in these marsupial animals there is one central, and the others surrounding.

The *Opossums* which have no pouch inclosing and concealing the teats, are smaller than those in which the females are furnished with that appendage; but, though the teats are exposed, the young are placed upon them, and adhere and grow there in a manner not very different from those which are enclosed in the pouch; and the abdomen is supported by marsupial bones in a similar manner. This circumstance shows that the pouch, that is, the external duplicature of the pouch, is not the essential part, but merely a protecting membrane; for it does not appear that the species that are without it carry their young with more difficulty than the others.

**THE MEXICAN OPOSSUM, OR CATOPOLIN**—*Didelphus dorsigera*. This species is about seven inches and a quarter in length; the eyes and surrounding spaces are brown, there is a line of the same colour up the middle of the face, and the sides of the head are brownish ash. All the upper part of the body is greyish yellow, and the under side yellowish; the ears are surrounded with yellow at the base, and the tail is spotted with brown and yellow, having a part near the insertion covered with hair, and the remainder naked and scaly. This is the species which is described under the name of the slender-tailed opossum by some naturalists.

**THE MARMOT OPOSSUM**—*Didelphus murina*. This species is less than the larger of European rats.—It is the murine opossum of Pennant and Shaw; and though smaller in size, it does not differ greatly in its general appearance from the species just mentioned. The muzzle is rather more pointed, the ears rounder, and the head more convex; the eyes are situated in the middle of a transverse band of black, which is broader above than under their openings, and does not extend far beyond their openings laterally.—The upper part of the body is a mixture of fawn and ash colour, the under part is whitish, but with a mixture of fawn which is gradually less and less conspicuous as it approaches the central part of the abdomen. These little animals are, however, subject to very considerable variations in the colour of their attire; and they have, on this account, sometimes been described under different names. The females are furnished with about fifteen teats, situated among the folds of skin in the groins; and the young ones, after they are discharged from the uterus, adhere firmly to these, like little round buttons, until they acquire the developed form of organised animals. The power of adhering to the mother is very wonderful in all the marsupial animals, but more especially in those which are not provided with a developed pouch; and after they have acquired some form, and are detached from

their permanent connection with the teats, these little animals may be observed holding on by the sides and legs of their mother, with a firmness that would not be expected in creatures which are apparently so small and so helpless. The species now under notice are inhabitants of the woods, in which they prey upon very small animals; and the mother may be seen with ten or a dozen little ones, riding on her sides or back, and she holding them on with her prehensile tail while she moves from branch to branch.

**THE THICK-TAILED OPOSSUM—*Didelphus macroura*.** This is a species considerably larger than the former, and though it has hitherto been described as a native of Paraguay, it is probable that, like the rest, it may be pretty generally distributed over the warmer parts of America. It is larger than the species last described, being about eleven inches in length. The tail is very thick for so small an animal, being not less than three inches in girth at the root. It is covered with hair of smooth texture for the first third, and the remaining two-thirds towards the tip are scaly, and it is all black, except an inch and a half at the point, which is of a white colour. The upper part of the body, the under part of the head, and round the eyes, are bright cinnamon brown; the face and the feet are of the same colour, but deeper. The cinnamon colour in the female is brighter than that in the males. The teats of the female are contained in an elliptic fold, and there are frequently more on one side than on the other. This species is said to be a little more energetic in its characters than some of the rest of the genus; but its manners, like those of most of the others, are imperfectly understood.

**SHORT-TAILED OPOSSUM—*Didelphus brachyura*.** This is a very small species, not exceeding five or six inches in length, and with the tail only about two inches and a half. It is understood to be that which is described by Buffon under the title of the *Touan*. The upper part of the body is blackish; the cheeks, broat, flanks, and inside of the thighs and paws are bright red; and the centre of the under part pure white. The female has not fewer than fourteen teats situated in the folds of the groin, which are absorbed when she ceases to suckle. The odour which the male emits, when irritated, is described as being very unpleasant. In some parts of the country these animals live in holes of the ground, which they dig for themselves, but in other situations where the surface is different, and there are hollow trees, they burrow in these.

***Delphinus pusilla*.** This species, though named by authors, and particularly described by D'Azzara as his No. 6 of these curious animals, is not so clearly established as most of the others. It is described as being about seven inches in length, exclusive of the tail, the last three inches of which part is naked and prehensile. A circle round the eyes is black, with white markings of the eye-brows, separated by a triangular spot of a dusky hue. The general colour of the body is that of the shrew, or a sort of dark mouse colour; it is described as inhabiting near the dwellings of the Indians in Paraguay, and throughout the greater part of the valley of La Plata, and having many of the characters of a common field-rat or mouse, at the same time that it retains the marsupial structure and characters, and the general appearance of the rest of the genus.

Such is a brief outline of most of the particulars which are known respecting the appearances, habits, and localities of this genus generally, and also respect-

ing the individual species of which it is made up. In an economical point of view they are animals of small value, though the fœtid odour of the living animal does not extend to the flesh, which is eaten by the Indians; but in a natural history point of view, they are far more interesting and important.

**DIDERMUM (Savigny).** A genus of molluscs united to the genus *Syrnecium* of modern authors.

**DIDYMOCARPÆÆ.** See CYRTANDRACEÆ.

**DIGITALIS (Linneus).** A well-known genus of European herbs, some of which are biennials, though the chief part are perennials. Linnæan class and order *Didymia Angiospermia*, and natural order *Scrophularia*. The foxglove is common on every hedge-bank, and no wild plant is more ornamental than this. In the gardens there is a white variety, though this is also found wild in some places. Two plants, namely, *Isoplexis Canariensis*, and *I. sceptrum*, were formerly ranked among the foxgloves, but are now separated by Dr. Lindley. All are easily propagated by seeds.

**DIGITARIA (Scopoli),** is the common finger-grass of Britain, and elsewhere.

**DILATRIS (Linneus).** A genus of greenhouse perennials from the Cape of Good Hope. Class and order *Triandria Monogynia*, and natural order *Hæmodoraceæ*. Generic character: calyx corolla-like, of six petals, hairy without, and regular; stamens six, inserted in the base of the calyx; three of them short and sterile, and three long; style filiform; stigma simple; capsule three-celled; seeds three or six pelate. The bulbs or tubers of this plant thrive best in sand and leaf-mould, and are increased by offsets or seeds.

**DILL.** Is the *Anethum graveolens* of Linneus, and is cultivated as a pot or sweet herb in gardens: it belongs to the same family as the fennel, so much used as a sauce for mackerel, &c.

**DILLENIA (Linneus).** A beautiful and large forest tree, a native of India, named in honour of J. T. Dillenius, once botanical professor at Oxford. It belongs to *Polyandria Polygynia*, and gives a title to one of the Jussieuan orders, viz., *Dilleniaceæ*.—Generic character: calyx of five, leathery, persisting sepals; petals five, and somewhat leathery; stamens very numerous, inserted into the receptacle; anthers oblong and erect; style none; stigmas dilated, persisting, and disposed in a circle; berry many-seeded and many-celled. This is one of our first-rate stove plants, and may be propagated by cuttings, or, which is better, by imported seeds, sown as soon as they arrive in this country. Mr. Sweet observes of this plant that the leaves are so delicate, that tobacco smoke, or a temperature below sixty degrees of Fahrenheit, injures them very much.

**DILLENIAEÆ,** a natural order of dichlamydeous dicotyledonous plants, containing sixteen known genera, and about one hundred species: It is closely allied to *magnoliaceæ*, from which it is distinguished by the want of stipules and the quinary arrangement of the parts of fructification. It also bears an affinity to *Ranunculaceæ*, but differs in its habit and in its persistent calyx.

The essential characters of the order are: perianth with an imbricated aestivation; sepals five, persistent, two exterior and three interior; petals five, deciduous in a single row, hypogynous; stamens numerous, hypogynous, arising from a torus, either distinct or polyadelphous, and either placed irregularly round the pistil or on one side of it; filaments filiform, dilated

either at the base or apex; anthers adnate, two-celled, the cells generally opening longitudinally and internally; ovaries definite, more or less distinct, with a terminal style and simple stigma; fruit consisting either of from two to five distinct unilocular carpels, or of a similar number cohering together, the carpels being either berried or two-celled; seeds ovate, arranged in a double series at the angle of the carpels or cells, two or many, sometimes solitary, surrounded by a pulpy arillus; testa hard; embryo minute, lying at the base of fleshy albumen.

The plants belonging to this order are: trees, shrubs, or under-shrubs. Their leaves are almost always without stipules, alternate, rarely opposite, commonly coriaceous, with strong veins running straight from the mid-rib to the margin. Their flowers are solitary, in terminal racemes or panicles, and often of a yellow colour. The greater part of these plants are found in New Holland. Some of them grow in India and in the southern parts of America and Africa.

In general they possess astringent properties.

The order has been divided into two distinct sections: 1. *Delimaceæ*, or *Delimææ*, including the genera *Delima*, *Tetracera*, *Davilla*, &c., in which the filaments are filiform, dilated at the apex, and bear on each side a round distinct cell of the anther. 2. *Dillenceæ*, comprehending the genera *Dillenia*, *Hibbertia*, *Pleurandra*, *Candollea*, *Colbertia*, &c., in which the filaments are not dilated at the apex, and the anthers are elongate and adnate.

The genus *Dillenia*, whence the name of the order is derived, furnishes six known species, some of which are applied to useful purposes. *Dillenia speciosa* is a splendid tree, forty or fifty feet high, found in the forests of Malabar and Java, which bears beautiful yellow flowers, larger than those of the water lily, and yields a pulpy acid fruit, the size of a large apple.

The tree has a thick stem and rugged bark, and when wounded discharges an astringent watery fluid. The calyx of this species, as well as that of *Dillenia scabrella*, when in a young state, has an agreeable acid taste, and is used in curries by the inhabitants of some parts of India.

*Hibbertia volubilis* is a green-house plant, well known for the beauty of its flowers and the peculiar fetid odour which they emit. *Hibbertia dentata* is a very ornamental green-house plant, and is admirably adapted for trellis; when supported with a stake, it will reach the height of six or eight feet, and has a beautiful appearance with its rich yellow flowers, which continue to expand during all the summer months.

Decoctions of the leaves and bark of *Davilla rugosa* and *elliptica* are used in Brazil as astringent washes for wounds and ulcers, and are applied to swellings of the legs which often occur in warm countries.

The leaves of *Delima sarmentosa* and several other species of that genus are so covered with asperities, that they are employed in China in place of a file, and are used for polishing furniture.

The fruit of many plants of this order when mixed with water is used in India as an acidulated drink in fevers.

**DILLWYNIA** (Smith). A genus of Australian evergreen shrubs, consisting of above eleven species, all introduced since 1794. They are decandrous plants, and belong to *Leguminosæ*. Generic character: calyx of two lips, and five-cleft; corolla standard

broad, unequally two-lobed; petals and stamens inserted in the middle of the calyx; style crooked; pod bellied, two-seeded; seeds like a string of beads. These plants thrive in moor-earth, and require well drained pots. Cuttings root freely in sand.

**DILUVIUM**. A term employed by geologists to describe one of the principal deposits which is found on the surface of our globe. A diluvial soil owes its existence to the violent action of water, or some other powerful agent operating for a considerable length of time on masses of the hardest bodies. Thus we find the most compact rocks, such as basalt, worn away and converted into an impalpable powder by natural processes, and at other times great blocks of granite removed from their earth-bound sites, and carried to distant plains, where such masses could not originally have been placed.

**DIMERA** (Latreille). In the first edition of the *Règne Animal*, the curious little family of coleopterous insects *Paelaphidæ*, was raised to the rank of a section under this name, from the incorrect observation of the tarsi, which were supposed to be only two-jointed. As, however, the observations of more recent authors proved them to be at least three-jointed, the section has been suppressed in the late works of Latreille.

**DINETUS** (Sweet). A genus of climbing plants, annuals, and perennials. They are pentandrous, and belong to the natural order *Convolvulaceæ*. Generic character: calyx in five parts; corolla bell-shaped, in five equal erect segments; stamens as long as the corolla, filaments joined to the tube; anthers roundish; style bifid; stigma headed; seed-vessel two-celled, four-seeded. The perennial species are increased by cuttings; the annual species are either greenhouse or open air plants, climbing quickly and producing flowers in autumn. This genus was formerly called *Porana* by Burmann, but separated by the late Mr. Sweet.

**DIOCTRIA** (Meigen). A genus of dipterous insects belonging to the family *Asilidæ*. (See this article under that of *BOMBYLIDÆ*.) The antennæ are placed upon a peduncle with the terminal style minute, and the basal joint longer than the following. The body is also long and narrow. They fly with great strength, and some of the British species have the wings black, and glossed with blue, which gives them a very exotic appearance. Their habits are similar to those of the *Asili*.

**DIODON**—globe fish. A genus of fishes belonging to the order *Plectognathes*, and family *Gymnodontes*, an account of which will be found under the last of these words.

**DIOMEDIA** (Cassini). A West Indian genus of evergreen shrubs, bearing yellow compound flowers, formerly ranked among the *Buphalmums* by Linnæus. These plants have silvery leaves, grow in light compost, and are propagated by cuttings.

**DIONÆA** (Linnæus). This genus of plants consisting of only one species, is found in Carolina in North America. It belongs to *Decandria Monogynia*, and to the natural order *Droseriaceæ*. The flowers are by no means striking, but the foliage is most remarkable, not only in form, but for its irritable properties, and consequent spontaneous motion. Each leaf is composed of three parts; a lower principal leaf, with two leaflets at its end. The leaflets are somewhat semicircular, and articulated close together upon a gland-like body at the point of the principal, as already stated. The articulations act like hinges, permitting the leaflets to fall back from each other, and remain in a nearly hori-

ontal position. While so spread open, should a thirsty or honey-seeking fly, or other insect, venture between the leaflets so as to touch the gland, they instantly start up together with considerable force, and clutch the prisoner; nor can the intruder easily extricate itself, because the inner edges of the leaflets are furnished with opposing ranks of short bristles, which shut into each other like the teeth of a rat-trap; so that a fly has no means of escape, more especially as the leaflets do not open again for many hours. The same motion is produced by touching the gland with the point of a straw or other body.

Some naturalists are of opinion that this extraordinary mechanism of the plant is a provision for supplying itself with putrified animal food; and have gone so far as make the plant catch morsels of raw beef or mutton, with a view to fattening, or increasing its volume. Nay, more, that the plants so feasted grew the better for it!—but this requires confirmation.

The vulgar name of the *Dionæa* is "Venus's fly-trap;" it is a low inconspicuous marsh plant, and, when cultivated in nurseries for sale, is planted in bog-earthly turf in a pot, kept constantly in a pan of water, as the plant must never be allowed to get dry; but by no means should it be ever flooded. Whether kept in a greenhouse or frame, they should have a hand-glass placed over them, to ensure a more equable degree of moist air: at the same time fresh air is necessary, the hand-glass never being kept quite close.

**DIONYX** (Dejean). A curious genus of minute coleopterous insects, belonging to the family *Pselaphida*, allied to *Stenists*, but having the labial palpi armed laterally with several spines; the antennæ have the four last joints very long. A single specimen of this curious insect has only yet been discovered: it was captured by Dejean, on the wing, in the evening, in the department of Aude, during his military campaigns.

**DIOPSIS** (Linnaeus). A genus of dipterous insects, belonging to the great family *Muscida*, and distinguished from every other dipterous genus by having the eyes and antennæ placed at the extremity of horny slender footstalks, rising from the sides of the head, and being in some species as long as the entire body, which gives these insects a very remarkable appearance. They are of great rarity, and seldom found in collections. They inhabit the tropical climates of India and Africa, and but little is known of their habits. Above a score distinct species are described in a monograph upon the genus, published in the last part of the Transactions of the Linnean Society.

**DIOSCOREA** (Linnaeus). A genus of herbaceous plants, some few of which are eminently useful to the inhabitants of the countries where they naturally abound. Linnean class and order, *Diacia Hexandria*, and natural order *Dioscoreæ*; Generic character; perianths superior, six-cleft, persisting; stamens inserted into the base of the perianths: filaments awl-shaped; anthers two-celled; styles simple; capsule triangular, three-celled, in each two compressed winged seeds. The *D. alata* is the yam of India. The tubers are as large as a child's head, rough and black exteriorly, but when boiled, remarkably white and mealy within, and very little inferior to the best potato. They affect light sandy land; and in some of the East-India port towns, may be had in considerable quantities for ship's stores, which keep well for a month or two on board ship. In our hot-house collections they are grown in light soil, and

trained up to stakes or upon a trellis, and are increased by parting the roots. These, however, are never cultivated for use.

**DIOSCOREÆ**, the yam family, a natural order of monocotyledonous plants, containing five or six known genera and upwards of fifty species. It is nearly allied to *Smilacææ* in structure and habit, but differs in the character of its ovary, its capsular fruit, and in its albumen, having a large cavity. In many respects it approaches the dicotyledonous structure.

Its essential characters are: flowers diœcious; perianth six partite; in the sterile or male flowers there are six stamens inserted into the base of the segments of the perianth; in the fertile or female flowers, the ovary is three-celled, each cell containing one or two seeds; style deeply trifid; stigmas undivided; fruit leaf-like, compressed, with two of its cells sometimes abortive; seeds flat, compressed; embryo small, included in a large cavity of the cartilaginous albumen, near the hilum.

The plants of this order are twining shrubs, with alternate, occasionally opposite leaves, which are generally reticulated with veins, as in the dicotyledonous plants. The flowers are small, spiked, and have from one to three bracteas.

They are found in tropical countries in both hemispheres, and possess in general mucilaginous and nutritive properties.

The chief genera of the order are, *Dioscorea*, *Rajania*, *Testudinaria*, *Oncus*, and *Æchma*. *Tamus*, or the black bryony, which was formerly included in this order, is by Loudon and others referred to a distinct order, called *Tameæ*.

*Dioscorea* furnishes numerous species which are found in the East and West Indies, and in North and South America. They are commonly known by the name of yams, and are interesting as furnishing large fleshy, sweet tubers, which are considered an important article of food in all tropical countries.

*Dioscorea sativa*, the common yam, is largely cultivated in the West Indies, where it serves for food to the negroes. It yields large thick tubers a foot broad, which have a mealy taste, and are esteemed nutritive and easy of digestion. They are eaten instead of bread, either roasted on the embers or boiled. The flour got from them is made into puddings. The flesh of the yam is white or purplish and viscid, but becomes farinaceous and mealy when dressed. The fresh juice of the root is acrid, and excites itching on the skin. There are many varieties of the root. *Dioscorea aculeata* is by some looked upon merely as an improved variety of the common yam. It is extensively cultivated, and yields tubers which are frequently three feet long, and weigh thirty pounds. All the edible species and varieties of *Dioscorea* are propagated in foreign countries like the common potato, but they arrive much sooner at maturity. They are planted in August, in rows two feet apart, and eighteen inches distant in the rows, and they are ripe in November or December.

*Testudinaria elephantipes*, common elephant's foot, is a native of the Cape of Good Hope, and is frequently cultivated in green-houses in this country. This plant has a singular appearance on account of its large fleshy root, a foot in diameter, which rises above ground and is covered with angular brown knobs having a tessellated aspect. The name *testudinaria* is derived from the resemblance between this root and the clumsy shell of some huge tortoise. The term

*elephantipes*, or elephant's foot, has also been applied on account of the remarkable appearance of this root-stock. The stem of the plant is slender and climbing, and presents a remarkable contrast to the root. The flowers are small and insignificant. The Hottentots, in time of scarcity, use the fleshy inside of the root as a sort of yam.

**DIOSMEÆ**—The Buchu family. A natural order of dicotyledonous plants, containing nearly twenty genera, and upwards of one hundred and twenty known species. It is closely allied to *Rutaceæ*, and by many botanists is considered merely a section of that order. It differs, however, in the peculiar structure of its fruit, and in having two ovules in each cell. It also bears an affinity to *Xanthoxyleæ*, *Simarubaceæ*, *Humiriaceæ*, and *Aurantiaceæ*.

The essential characters of the order are: flowers hermaphrodite, regular or irregular; calyx consisting of four or five divisions; petals as many, distinct or united, rarely wanting; æstivation generally twisted, convolute, rarely valvate; stamens equal to, or double the number of the petals, sometimes, by imperfection, fewer, hypogynous, or rarely perigynous, placed on the outside of a disc or cup surrounding the ovary, and either free, or combined with the base of the calyx, or sometimes wanting; ovary sessile, stalked, its lobes equal to the number of petals, or fewer; ovules twin and collateral, or one above the other, very rarely four; style single, sometimes divided at its base into as many parts as there are lobes of the ovary; stigma simple or dilated; fruit consisting of several capsules, either cohering firmly, or more or less distinct; endocarp, or internal skin of the fruit, entirely separating from the sarcocarp (or fleshy matter under the skin), which opens internally by two valves; the endocarp also two-valved, the valves opening at the base, but connected by a membrane which bears the seeds; seeds twin or solitary, with a testaceous integument; embryo with a superior radicle, which is either straight or oblique; no albumen.

The plants belonging to this order are trees or shrubs, rarely herbs. They are furnished with exstipulate, opposite, or alternate simple or pinnate leaves, which are covered with pellucid resinous dots. Their flowers are axillary or terminal, and of a white or reddish colour.

The greater part of them inhabit the tropical parts of the globe. They are found abundantly in the warm regions of America, at the Cape of Good Hope, and in New Holland. A single genus is found in the south of Europe.

By some authors this order has been divided into sections according to the countries in which the plants are found. Thus we have, first, the European section, including the genus *Dictamnus*, found in the south of Europe; second, the Cape section, including the numerous species of *Diosma*, *Adenandra*, &c., found at the Cape of Good Hope; third, the Australasian section, comprehending the genera *Boronia*, *Phebalium*, *Correa*, *Eriostemon*, &c., found in New Holland and Van Diemen's Land; and, fourth, the American section, including the genera *Evodia*, *Galipea*, &c., which grow in South America, the West Indies, New Zealand, the Friendly Islands, and Mexico. To this last section are referred the *Cuspariæ* of Decandolle. This division of the order, according to the geographical distribution of the plants, is found to agree most remarkably with the character of their fructification.

In general the plants of this order abound in essential oil, and possess aromatic, tonic, and antispasmodic properties. Many of them have been used in medicine.

The genus *Diosma*, or Buchu, furnishes upwards of seventy species, almost all of which are natives of the Cape. They have a powerful and offensive odour, which is nevertheless relished by the Hottentots. Many of them have been recommended as antispasmodics and tonics.

The leaves of *Diosma crenata* (*Barosma crenulata* of recent authors) resemble much those of senna, and are used in medicine under the name of Buchu leaves. They have been introduced into the Dublin Pharmacopœia. The emit a strong aromatic odour, have a pungent taste, and yield by distillation a volatile oil. They possess diuretic and tonic properties, and have been recommended in the form of infusion and tincture in some diseases of the bladder. Their activity seems to be owing to the volatile oil and resin which they contain. *Diosma ericoides* and other species are used by the Hottentots to scent the ointments with which they anoint their skin.

*Galipea*, or *Cusparia febrifuga* (*Borplandia trifoliata* of Willdenow), is a handsome South American tree, and yields the well-known Angostura or Cusparia bark. This bark occurs in commerce in pieces from six to twelve inches long. It is of a fawn colour, and is covered with a whitish rough epidermis. When powdered, it exhibits a yellowish brown hue. It has an aromatic, bitter, and somewhat astringent taste. According to analysis, it consists of cinchonia, and a small quantity of brucia, combined with iganuric acid, muriate of ammonia, gum resin, extractive and volatile oil. The term Angostura bark is derived from the common name of the town of St. Thomas, near the Straits of the Orinoco, whence it is exported; while Cusparia is derived from the native name of the tree. A spurious kind of cusparia bark is sometimes met with in commerce, which possesses poisonous properties, and appears to be the product of a species of *strychnos*. The epidermis of this false Angostura bark is covered with rust-coloured warty excrescences; its powder is of a very light yellow, and it has neither the odour nor the aromatic flavour of the true bark. The lichens which grow upon it, and the effect of different chemical agents, are also sufficient to distinguish it.

Angostura bark possesses all the tonic properties of Peruvian bark, and is used as an aromatic bitter in stomach complaints, as well as in intermittents and dysentery. It is frequently combined with rhubarb, magnesia, and carbonate of potass, and is prescribed in the form of powder, infusion, or tincture.

*Evodia febrifuga*, *Ticorea febrifuga*, and *Hortia Braziliæna*, yield barks which are used in Brazil in the cure of intermittent fevers.

The root of *Dictamnus albus*, or *Frasinella*, has a bitter aromatic taste, and was formerly used medicinally as a sudorific and vermifuge. This plant abounds so much in volatile oil, that the atmosphere surrounding it actually becomes inflammable in hot dry weather.

**DIOSPYRUS** (Linnæus). Is the date-plum, a genus of trees and shrubs, indigenous to many different parts of the world. Linnæan class and order, *Polygamia Diœcia*, and natural order *Ebenaceæ*. In our collections they are placed in the stove or greenhouse, and are in these places treated like other plants. The hardy ones are seen in our shrubberies,

and grow to good-sized shrubs. Some of the species are cultivated for their fruit in the eastern parts of Asia, and the *D. ebenum* yields the valuable timber called ebony.

**DIPLOLEPIS.** A name introduced by Geoffroy for the gall-flies, which Linnæus had previously termed *Cynips*. The former name, notwithstanding its incorrect application, having been adopted by the French entomologists, has occasioned much confusion between these insects and those of the family *Chalcididae*, which Geoffroy misnamed *Cynips*. See the articles *CHALCIDIDÆ* and *CYNIPIDÆ*.

**DIPLOPTERA** (Latreille). A division of stinging hymenopterous insects, comprising the various species of wasps, and distinguished by having the upper wings folded longitudinally when at rest. The antennæ are generally elbowed and thickened at the tips: the eyes are notched on the inside. The collar is produced behind on each side as far as the base of the wings, the upper pair of which have two or three closed submarginal cells; the body is smooth and polished without hairs (as in the bees) and, generally, of a black colour, more or less spotted with yellow or brown. The character upon which this division is founded, and from which it received its name (doubled wing), is one of those curious instances where we find a peculiarity of organisation which cannot, so far as we are enabled to perceive, have the slightest influence upon the habit of the species, and yet it is so constant that we look in vain throughout the whole of the extensive order *Hymenoptera* for any other instance of folded wings except in the group in question: and yet, if we look at the habits of the species, we find them to be sufficiently diversified to induce us to suppose that we might here find sufficient cause for such a marked peculiarity: but this is not the case. Thus, we find the *Odyneri* perfectly resembling the *Crabronidæ* and *Cercerides* in the economy of burrowing into sand and wood, in order to form the cells in which they lay up a provision for their progeny, which are to be hatched from eggs deposited at the same time with the food; whilst, on the other hand, in the *true* wasps, we have a social economy, similar to that of the hive.

The *Diploptera* then, in respect to their habits, form two groups; but Latreille has established two sections from the structure of the antennæ, which in the first (*Masarides*) have the terminal joints soldered together, so as to form a club; whereas in the second (*Vespides*), including both the *Odyneri* and *Vespæ*, the antennæ have the joints distinct and composed, as usual, of thirteen joints in the males, and twelve in the females.

**DIPLOTHEMIUM** (Martius). Is a genus of Brazilian palm, to which country it is confined; nor is its history much known.

**DIPPER**—*Cinclus*. A genus of birds belonging to the *dentirostral* division of Cuvier's great order *Passeres*, and to the thrush family in that order. The singular appearance and very peculiar habits of these birds render them objects of much attraction, not merely to professed ornithologists, but to all who are fond of observing the children of nature in their wild state. Accordingly these birds have received a great many popular names; and systematists have been as much puzzled, in what part of their artificial cabinets to give them a place. The fact of these birds having separate names in both the ancient and both the modern languages, which are spoken in Britain, is sufficient to prove the attention which they must have attracted

even at a very early period. This bird is the *Mwy-alchen y dwfr* of the Welsh, and the *Gobha uisge* of the Scotch Highlanders; in England it is the water ouzel, the penrith ouzel, the water crake, the water crow, the water colly, and a variety of other names; and with the Scotch it is the water pyet, the water craa, and various other names. In fact, in this country alone, it has got as many names as might suffice for a tolerably well-stocked aviary.

The generic characters are, the bill of mean length, sharp in the cutting edges, straight, elevated in the culmen, rounded at the extremity, and with the point of the upper mandible bent over that of the lower. The nostrils are lateral at the base of the bill, longitudinal, and in great part covered with membrane. There are three toes to the front and one to the rear; the tarsi are short, but longer than the middle toe. The wings are short and rounded, the first quill being short and merely a supporter to the second, and the third and fourth the largest in the wing. It is doubtful whether there is any more well made out species than one. Several have indeed been mentioned, but without sufficient grounds, as it should seem; and that which is mentioned as being an inhabitant of the peninsular Crimea on the north of the Black Sea, and named after Professor Pallas, by Temminck, differs from that met with in this country only in the colour, being all over of a rich, reddish brown, while our one is pied. The habits of the two are, however, described as being so nearly alike, and so little is known of the one named after Pallas, that a description of the one which, though not common in any part of Britain, is pretty widely distributed over it, will suffice for popular purposes.

*Cinclus aquaticus*, the dipper, is very generally dispersed over Europe, seems capable of enduring all climates, and is understood to be resident all the year round in most of the localities in which it inhabits. With us, it may be described as being chiefly a mountaineer; but it is not so on many parts of the continent, for it is found in Holland, in Jutland, and in many of the comparatively flat districts on the south of the Baltic and in Russia. It is also met with in the south, as in Spain, Italy, and the island of Sardinia, being particularly abundant by the banks of the smaller streams in the Pyrenees and the Alps. It is not, however, confined to the south and middle parts of Europe, for it is met with in the Faro islands, and it is not improbable that it may occur in Iceland. It occurs also in northern and central Asia, from Siberia to the north of Persia, though, from the habits about to be described, it is not found in the dry deserts.

The dipper bears some resemblance in its general shape to the common wren, only the tail is shorter in proportion. The whole length, if we take the average of full-grown birds, is about eight inches, the stretch of the wing about ten or eleven, and the weight about two or three ounces. The colours are, the head and back part of the neck amber brown; the back and scapulars black, but with blackish grey on the margins of the feathers; the throat, a small patch on the eyes, the sides of the neck, and the upper part of the breast, white; the lower part of the breast and the rest of the under part of the body is chestnut-brown, passing into dark brown nearly black toward the vent, and having the under tail-coverts of nearly the same grey as the margin of the feathers on the back. The bill is blackish brown; and the tarsi and toes grey, sometimes inclined more to yellow, and sometimes to

blackish blue. The female is very like the male, except that the head is darker brown, and the white on the breast dull coloured. The young are grey on the head and part of the back, and have more white on the breast, but it is broke by mottlings, and they have also some white on the margins of the wing-feathers.

Dipper.

These birds breed early in the season, and construct their nests in general early with a great deal of care. The nest is formed under a projecting stone in a hole of the rock, or even in a hole of the wall, if the situation is sufficiently retired and near the water. This nest usually consists of a great quantity of materials, generally vegetable, as the stems and leaves of aquatic plants, dry moss, and the leaves of trees; but the structure is differently described by different authors, and may be different in different circumstances and under different exposures. Of course we do not know the instinct which leads birds to build nests differing so much from each other as they are in different species, or indeed what leads them to build nests at all; but as they must in some manner be regulated by circumstances, they will, of course, make their structures in accordance with these. If the nest is immediately under a projecting roof, it is natural to suppose that though the bird might give it a dome in a more exposed situation, it might be satisfied with a natural one where that presented itself. The eggs are described as being four or five, of a pure white colour, semi-transparent, long in their shape, and very much pointed at their small ends. This is sufficient to show that there is not much philosophy in an opinion sometimes advanced, that the form of the egg bears some analogy to that of the bird; for the dipper is in every way a short bird in its body, its wings, and its tail. The young dippers are ravenous eaters; and the nest with young in it is easily detected by their chirping.

Dippers are with us found only in the streams of hilly countries, which run over beds of sand or gravel, and have their waters clear and transparent; and it is an especial frequenter of those little pools between the rapids, where trouts resort to deposit their spawn.—The spawn of fishes, their fry, when young and in the breeding pools, and water insects, are understood to form the chief subsistence of the dipper; and as this kind of provisions is found more early in the season than almost any other food for an animal feeding bird, the dipper is enabled to find food for its young sooner in the year than those birds which resort

to the hill and the brake in those localities. Indeed, though it is confined to the margins of streams, and to those of streams of a particular character, and therefore not distributed in breadth over any part of the country, the dipper runs less hazard from famine than most other birds, except in severe winters, when it is frozen out. This, too, is a circumstance of rare occurrence in most of the haunts of the dipper; because, in most of those localities in which it delights, which are the dells of the secondary hills, not far from the low country, but always above those places at which the bottom begins to be oozy, and the water turbid with mud, there are always springs breaking out from such a depth as that they seldom freeze; and there are many little animals which intrust their young to such springs, and thus, in case of necessity, furnish the dippers with food until the frost breaks.

If the rivulet is open, the dipper is perfectly independent, because it can procure its food under the water as readily as on the bank. It is true that it is not web-footed, and consequently it is not a swimmer, neither are its general characters those of a water bird. Still it is a bird which can turn the water to great account, and it seems to know this as well, for it is apparently never happy but when the water is immediately within its reach, and always happy when it is so. It is seldom seen at any great distance from its favourite rivulet; and when it is found at some little distance it is timid, as if it were without the security of that which forms its castle. When, however, it is near the water, it is far from being a shy bird; but, though it is very easily seen, it is by no means easy to catch.

Its usual action when sitting on the points of the little pieces of rock and detached stones in the pools, consists of a continual bending down of the head, and a flirting up of the tail at the same time; and it is from this peculiar motion of the head, and not from the fact of its getting into the water, that it is called the dipper. From the shortness and broadness of its wings, and the compactness of its body, it gets very quickly into flight, and it skims along the surface of the water, almost touching with its wings at every stroke; and, when flying in this manner, it appears to get on more rapidly and with less fatigue than when it is higher above the surface. It is highly probable that all birds which have this habit of skimming along the surface of the water, find a relief in so doing, not only from the cooling, but from the greater resistance which is there offered to the down stroke of their wings, from the difficulty with which the air escapes from between the wing and the water.

The dipper can get under water with great facility, and walk along the bottom, and probably also come to the surface, and take wing from the water; though in general it comes to the bank for this purpose. Its plumage is very waterproof, and it is never wetted or ruffled by these immersions, one of which would effectually prevent the flight of any ordinary land bird. It has sometimes been objected to this under-water habit of the dipper, that as it cannot swim on the surface like the aquatic birds properly so called, or run on the surface like some of the long-toed birds, it cannot get below, because it is specifically lighter than the water, and has no purchase of the feet from which to thrust itself down; but the dipper turns its head and its wings to very good account in performing this operation. The dipping motion of the head gets that part under water; and the wings are partially under water at the same time. Then the elevation of the head,

and the raising of the wings, converts these into levers for the depression of the body; and by this means it gets very speedily under water,—so speedily, indeed, that it appears to run down the bank to the bottom with no more apparent effort than what is necessary for simple progressive motion. When it is overhead in the water, the wings, and partially also the head are used with great neatness and effect; and the upward stroke of the wings, even in that case, serves to keep the body to the bottom against any difference of gravitation there may be between the bird and the same bulk of water. In this way it can pick up and even pursue its food below water as easily as a common ground bird can do on the surface of the earth; and as, when below the surface, it always holds the wings recovered, that is, at such a distance from the body as that they can strike first either upwards or downwards, it can move with equal celerity in any direction. This need excite no surprise; for though wings are not the usual instruments of motion below water, yet the difference between the wings in the air and in the water is more a question of their being proof against the action of water than of any thing else, because in the matter of specific gravity, it requires no very great degree of mechanical acumen to perceive, that it is not more difficult for a bird, by muscular exertion, to keep itself down in a fluid specifically heavier than itself, than it is to keep itself up in a fluid specifically lighter; and, as the difference between the specific gravity of the dipper, and that of water, is really less than the difference between the specific gravity of any bird and air, the dipper has an easy task. We forgot to mention that the dipper is a sort of songster in the early part of the year, though not a very melodious one; yet it is cheerful to hear a bird sitting on a stone in the brook and singing, when the banks of that brook are covered with snow. The summer note is a mere chirp.

**DIPSACEÆ.** The teasel or scabious family, a natural order of dicotyledonous plants, containing eight genera, and nearly one hundred and twenty known species. It is closely allied to *Compositæ*, but differs in its distinct stamens and pendulous albuminous seeds. It also bears an affinity to *Calyceæ*, from which it is distinguished by its free anthers and inverted embryo. It bears likewise a relation to *Valerianææ*, but differs in its habit, its capitate flowers, and in having an involucrellum. By these characters it is also separated from *Caprifoliaceæ*.

Its essential characters are: calyx superior, membranous, resembling pappus, surrounded by a scarious involucrellum. (This involucrellum is a peculiar organ, resembling an external calyx, and may be said to correspond in some degree with the partial involucre of the *umbelliferae*.) Corolla monopetalous, tubular, inserted in the calyx; limb oblique, four or five lobed, with an imbricated æstivation; stamens usually four, inserted into the tube of the corolla, alternate with its lobes; anthers distinct, two-celled; ovary inferior, one-celled, with a single pendulous ovule; style filiform; stigma simple, longitudinal or capitate; fruit dry, indehiscent, one-celled and one-seeded, crowned by a pappus-like calyx; albumen fleshy; embryo straight, radicle superior.

The plants belonging to this order are herbs or undershrubs, with opposite or verticillate leaves, and densely capitate flowers, which are surrounded by a many-leaved involucre.

They abound in the south of Europe and north of Africa. Some are also found at the Cape of Good

Hope and the Levant. In general they shun cold, and do not reach a great elevation above the sea.

Their properties are not deserving of much attention. Many of them are bitter and tonic, some are used on account of their astringency in dyeing, and a few possess febrifuge virtues.

The chief genera of the order are *Dipsacus*, *Scabiosa*, *Knautia*, *Morina*, and *Pterocephalus*.

The genus *Dipsacus*, or teasel, includes thirteen species, of which three are natives of Britain. *Dipsacus fullonum*, fullers' teasel, is so called on account of being used in dressing cloth, for which purpose the hooked scales of its receptacle are admirably adapted. These are fixed round the circumference of a large broad wheel, which is made to revolve, while the cloth is held against them. By long cultivation in a poor soil, the hooks of the receptacle are said to disappear. By some botanists this species is looked upon merely as a variety of *Dipsacus sylvestris*, or the common wild teasel. *Dipsacus pilosus*, small teasel, is the handsomest species. Its seeds are eaten by small birds. The axils of the leaves of the common teasel usually contain a quantity of limpid water, which is sometimes very acceptable to travellers.

The genus *Scabiosa*, or scabious, includes sixty-one known species, only two of which are natives of Britain.

*Scabiosa succisa*, Devil's-bit scabious, is common in meadows and pasture land. It derives its name from the circumstance of its root being as it were cut or bitten off abruptly. It is said to yield a green dye, and also to be sufficiently astringent for tanning.

*Scabiosa atropurpurea* is rather a handsome species, bearing dark purple flowers, and is cultivated as a border annual or biennial. The leaves of *Knautia arvensis*, common field scabious, have a sharp and rather bitter taste, and were formerly recommended in cutaneous diseases.

**DIPSACUS** (Linnæus). A genus of European herbs, one of which is the well-known clothiers'-brush, or teasel, found wild as well as cultivated in England. It belongs to the fourth class and first order of Linnæus, and gives a title to an order in the natural system, namely, *Dipsaceæ*. Some of the species are admitted into the flower-garden, and are raised from seeds. The cultivated teasel is, like the rest, a biennial, and is sowed in drills, and kept clean and thinned by the hoe in the first year; in the second, the plants are also kept clean, and when the heads are ripe, they are cut for sale.

**DIPSAS** (Leach). A genus of molluscs now forming a subdivision of the genus *Anodon*, under which it is described.

**DIPTERA.** An order of insects belonging to the great division *Haustellata*, or those furnished with a tubular proboscis, and distinguished by the presence of only a pair of membranous extended wings affixed to the centre of the sides of the thorax, and generally furnished near their insertion with a pair of short clubbed organs, termed halteres or balancers, respecting which, as analogically representing the posterior wings of the four-winged insects, entomologists are at variance; the mouth is provided with a sucker composed of from two to six scaly lancet-like pieces, and enclosed in a canal upon the upper surface of a fleshy proboscis, or covered by one or two articulated plates which serve as a sheath (*Hippobosca*). The body is composed, as in the other six-legged insects, of three principal divisions representing the head, thorax, and abdomen. The ocelli, when present, are generally three in number; the antennæ exhibit various

degrees of development, from the exceeding length in the *Macroceræ* and *Megistocera* to the scarcely visible size in the *Hippoboscæ*. In the *Typulidæ* we find these organs composed of numerous articulations.

A, Antennæ of *Tipula*; B, of *Tabanus*; C, of *Musca*.

In the *Tabanidæ* and *Beridæ* they are very short, and the terminal articulations become almost indistinct, so that in the *Muscidæ*, &c., where they are very short, and appear to be composed only of three joints, having a terminal bristle, it is impossible not at once to perceive that the terminal joints are, with the exception of those composing the seta, so entirely soldered together that their union is not visible. The eyes are lateral, and in many instances those of the males are much larger than in the females, uniting upon the crown of the head. In others they are so large as to occupy nearly the entire head, leaving but a small space only for the mouth.

In those species which have the mouth more perfectly developed than the rest, and which consist of the blood-thirsty gnat and gadfly, we find a series of organs, greatly modified of course as to their form, in order to fit them for their functions, but which, as to their number, correspond with those of the mouth of the true mandibulated insects, so that it is equally impossible for us to arrive at any other conclusion than that the parts of the mouth of the fly represent, in an altered state of development, the parts of the mouth of the beetle. We accordingly find that the mouth in *Tabanus* consists of a large fleshy organ, having a fleshy pair of lobes at its extremity, and which, being the lowest part of the mouth, corresponds with the lower lip of the beetle. At the sides of this, and rather higher in the mouth, is attached a pair of lancet-like organs, having a pair of large biarticulate palpi arising from the base,—these constitute the maxillæ and the maxillary palpi. Still higher in the mouth another pair of lancets appears, which represent the mandibles, whilst a larger horny piece, channelled beneath for the reception of the others, and which forms the upper lip (*labrum*). Within the mouth another very fine lancet appears, analogous to the tongue of the grasshoppers, an organ seldom developed to any extent in the *coleoptera*. When we consider the habits of these insects, it is evident how necessary it is that the organisation of the mouth should be fitted for a different employment from that of masticating. These habits are essentially suctional, and the food of the insects is essentially fluid; broad horny organs would therefore be useless, whereas a series of acute instruments for puncturing and penetrating deeper and deeper into the food, and a fleshy canal, up which, by suction, fluids easily pass, is what would exactly be looked for in the workmanship of an omniscient and all providing Artificer.

In other groups of dipterous insects, and more especially in those which prey upon their companions (*Aritidæ*, *Empidæ*, &c.), we find diminished forces

in the organisation of the mouth, the lancet-like mandibles have vanished, but all the remaining organs appear in full development. In the *Syrphidæ* the maxillæ become smaller, and in *Musca* they are

A, Mouth of *Tabanus*; B, of *Musca*.

completely lost. In the *Æstridæ* the entire mouth is sometimes completely obliterated. The legs are generally long and slender; some instances occur when then are disproportionately long, whilst in others they are more or less thickened and spined. The wings agree in their veining with the anterior pair of the *Hymenoptera* rather than with those of the *Neuroptera*, only there are fewer transverse nerves. In one group however, *Nemestrina*, the wing is reticulated nearly as much as in the *Neuroptera*. In comparing the upper wing of a bee with the wing of a fly, no particular resemblance is to be traced between the direction and position of the veins, but if both the front and hind wings of the bee be compared together with the wing of some flies, as the *Syrphidæ*, and particularly *Aphrites*, we are enabled to trace a very great resemblance between them in this respect. M. Macquart employs this circumstance as a forcible argument in support of the opinion that the balancers of the *Diptera* do not represent the lower wings of the bee. The uses to which these balancers are applied are not yet decidedly ascertained; the insect moves them with extreme rapidity, especially when a buzzing noise is produced, and it is important to observe that they are placed close to the mouth of a pair of the breathing pores. Many species are moreover provided at the base of the wings behind with a pair of membranous doubled organs, somewhat like the valves of a shell, which are termed *alule*; one of these is attached to the wing, and the other to the sides of the thorax. The size of these alule is in inverse proportion to that of the *halteres*. The abdomen is generally attached to the thorax by a portion only of its basal diameter, it is composed of from five to nine visible articulations, and is generally pointed at the extremity of the females, enabling them the more readily to introduce their eggs into the situations in which they are deposited. In those species which have the abdomen composed of the fewest segments, those which appear to be wanting are transformed into a kind of ovipositor, consisting of a series of little tubes sliding one into another like a telescope. The sexual organs of the males are external in many species, and folded beneath the abdomen. The legs are terminated by a tarsus consisting of five joints, the last of which is armed with two small claws, and very often with two or three membranous lobes or pulvilli. It is by the assistance of these terminal organs of the foot that the fly is enabled to perform the curious mechanical feat of walking with the back downwards, against gravity, upon the ceilings of rooms, highly polished glass, &c. From the experiments of Sir Everard Home, it has been generally considered that this was effected by the formation of a vacuum, by means of

the close application of the margins of these soles of the feet as we may term them, and the subsequent muscular raising up of their central parts; but the following remarks by one of our most acute modern observers, Mr. Blackwall, published by him in the Appendix of the last volume of the Linnæan Transactions (in correction of a memoir previously published by himself, in which he had adopted the vacuum system), will be read with interest, as showing what interesting sources of inquiry are opened to the student of nature, even in the commonest objects of the creation.

In experimenting upon the house-fly, he observed that individuals frequently remained fixed to the sides of an exhausted glass receiver after they had entirely lost the power of locomotion, and an evident distension of the abdomen had been occasioned by the exhaustion of the aeriform fluids it contained. To detach them from these stations, the employment of a small degree of force was found requisite.

"In prosecuting this subject, clean phials of transparent glass, containing spiders and various insects in the larva and imago states, capable of walking on their upright sides, were breathed into, till the aqueous vapour expelled from the lungs was copiously condensed on their inner surface. The result was remarkable; the moisture totally prevented those animals from obtaining any effectual hold on the glass, and the event was equally decisive if a small quantity of oil was substituted for the aqueous vapour. A similar consequence ensued, also, when the flour of wheat, or finely pulverised chalk or gypsum, was thinly strewn on the interior surface of the phials, the minute particles of those substances adhering to the tarsal brushes of the spiders, the pulvilli of the perfect insects, and the under side of the feet of the larvæ. These facts, far from corroborating the mechanical theory, appeared quite inexplicable, except on the supposition that an adhesive secretion is emitted by the instruments employed in climbing. The next point to be determined, therefore, was, whether spiders and insects in the larva and imago states, when moving in a vertical direction on clean glass, leave any visible track behind them? Careful and repeated examinations, made with lenses of moderately high magnifying powers, in a strong light, and at a favourable angle, speedily convinced me that my conjecture was well founded, as I never failed to discover unequivocal evidence of its truth, though, in the case of the spiders, considerable difficulties presented themselves in consequence of the exceedingly minute quantity of adhesive matter emitted by the brushes of those animals. On submitting this secretion to the direct rays of the sun, in the month of July, and to brisk currents of air, whose drying power was great, I ascertained that it did not suffer any perceptible diminution by evaporation under those circumstances. Now, it is reasonable to infer, from the foregoing researches, that the hair-like appendages constituting the brushes of spiders, and occurring in such profusion on the inferior surface of the pulvilli of insects, are tubular."

The larvæ of the diptera, as well as the perfect insects, have characters peculiar to themselves. In many of these larvæ the head is of a fleshy substance, without any determinate form, whilst in the majority of the larvæ of other orders the head is horny and consistent in form. The breathing pores have also a peculiar disposition; instead of

being placed in pairs upon the first, fourth, and following segments of the body, as is generally the case, the anterior pair are found upon the second segment, whilst all the rest, from two to eight in number, are brought together upon the terminal segment. Those larvæ, which are constantly footless, or but rarely provided with fleshy appendages, have the mouth armed with two points formed for piercing the matters upon which they feed. In the transformations which these insects undergo in their passage to the perfect state, there is less diversity than in the organisation of the perfect insect. Insects in general are oviparous, but there are of course exceptions to this rule, and two of the most remarkable are to be found in this order. We have already, in our article upon the BLOWFLY, detailed one of these exceptions, in which the eggs are hatched in the body of the parent, and produced in a living state. The other occurs in the forest-flies (*Hippoboscidae*), in which group not only are the eggs hatched within the body of the female, but the larva there acquires its full growth, and assumes the pupa state, being ejected from it in the shape of an egg as large as the abdomen of the parents, and from which the perfect insect, instead of the larva, makes its escape.

The larvæ of the diptera in general offer so great a simplicity of structure, as to cause an uniformity of appearance; nevertheless, those which reside in the water are more diversified in their characters, being furnished with organs of nutrition and respiration very unlike those of the terrestrial larvæ; for an account of which we must refer to our articles upon CHIRONOMUS, CULICIDÆ, CORETHRA, &c.

In passing to the pupa state, these larvæ employ two principal modes. In the greater number there is no shedding of the skin; the skin of the larva hardens, contracts, and becomes an oval cocoon, within which the pupa is disengaged, appearing at first merely as a gelatinous mass, but afterwards exhibiting in some degree the different parts of the perfect insect, the eyes and wings being folded upon the breast. In the others the metamorphosis is effected by the larva shedding its skin, and the insect then appearing in the form of an inactive incomplete pupa, like that of the former, but not inclosed in a cocoon. In some of the latter, as in the aquatic species, the pupa retains its activity, jerking about with much agility in the water, whilst many are quite inactive.

In their perfect state, the insects of this order are scarcely less numerous, in point of *species*, than any other order of insects; but, if we look at them with respect to the number of *individuals*, we find them infinitely to exceed any other. The clouds of midges, for instance, rising at eventide over the marshes, like the incense of the Temple, equally pay homage to the Divinity, in showing forth His mighty power; whilst myriads of flies of every kind are to be found in every quarter of the globe, traversing plants and every animate object, and more particularly all that has ceased to live.

This immense profusion with which they are dispersed over the globe causes them to fulfil two very important functions in the economy of nature; first, they serve for food to a vast number of the higher animals. Charged with a Divine mission by Him "who giveth food to the young bird," the swallow and the sparrow destroy them by myriads, and the

fly-catcher and the humming-bird alike find in them a constant shedding of manna; whilst, on the other hand, they cease not in effecting the disappearance of all substances in a state of decomposition, both animal and vegetable. They are universal scavengers; and so great is their activity and the rapid succession of their generations, that Linnæus might well say that three flies can consume a horse as fast as a lion. Amongst such a vast number of objects, it is not surprising that some should be found obnoxious to ourselves or our properties. Many species, accordingly, cease not to make man their prey, by sucking his blood, whilst some either attack our cattle in like manner, or deposit their eggs upon their bodies, within which the parasitic larvæ feed; others deposit their eggs, or young, upon our food and upon our growing corn.

Many species reside in woods, in meadows, marshes, and in our habitations, others move with dancing feet upon the spray of the waves, and even upon the snows of the polar regions. Many are attached to plants, upon the flowers of which they abound, sucking the honeyed sweets, without giving the preference to any particular plant, whilst some are confined to a single species of flower; but it is upon the star-like anthemids of our meadows that the majority seem to revel with the greatest delight. During the summer and autumn the flies are attracted to our orchards, in order to destroy our fruits, whilst some species delight in the honey dew of the aphides, or the fluids which escape from the wounds of trees. The domestic fly alike feeds upon all kinds of household provisions; and other species, which so closely resemble it in size and appearance as to deceive an ordinary observer, are parasitic upon the nests of various solitary bees. Nothing, indeed, can be more amusing than to watch one of the latter following the laborious insect, the young of which she is about to supplant by her own, peering about into the mouth of the nest, and cautiously making her entrance, in order to deposit her own eggs, when the bee has, with great toil, completed her nest, and deposited her store of honey-paste for the food of her own progeny.

The order was established by Aristotle, the great father of zoology, under the name which is still retained for it; and since the days of Linnæus, by whom its distribution was attempted, various naturalists have contributed to raise it to the rank which it has now attained, although it has not been a general favourite with our amateurs. It is to Reaumur and De Geer that we are indebted for our knowledge of the transformations of many of these insects; whilst Fabricius, Latreille, Meigen, Fallen, Wiedemann, Robineau des Voidy, and Macquart, have successively established families, tribes, genera, and species; the works of Meigen and Macquart having especially contributed to this end.

The following is the arrangement proposed by the latter in his valuable "Histoire Naturelle des Diptères," published during the present year, and which we have adopted, with this variation only, namely, that, with Latreille and Leach, we have considered the forest-flies as forming a primary section of the order, whereas M. Macquart has placed them merely as a family of the great group of *Muscidae*.

Section I. (*Ovipara* or *Larvipara*); DIPTERA, Leach.

Head distinct from the thorax; sucker enclosed in a labial canal; claws of the tarsi simple, or with one tooth; the transformation to the pupa state not taking place within the body of the parent.

Division 1. (NEMOCERA). Antennæ having six or more distinct joints; palpi with four or five joints.

Fam. 1. (*Culicidæ*). Sucker with six lancets.

Fam. 2. (*Tipulidæ*). Sucker with two lancets.

Division 2. (BRACHOCERA). Antennæ having three distinct joints; palpi with one or two joints.

Subdivision 1. (*Hexachæta*). Sucker with six lancets. Fam. *Tabanidæ*.

Subdivision 2. (*Tetrachæta*). Sucker with four lancets.

A (Fam. *Cænomyidæ*, *Beridæ*, *Stratiomyidæ*).

B (Fam. *Mydasidæ*, *Asilidæ*, *Hybotidæ*, *Empidæ*, *Henopidæ*, *Nemestrinidæ*, *Bombyliidæ*, *Anthraxidæ*).

C (Fam. *Therevidæ*, *Leptidæ*, *Dolichopidæ*, *Syrphidæ*).

Subdivision 3. (*Dichæta*). Sucker with two lancets. This subdivision comprises an immense assemblage of species, constituting the Linnæan genera *Estrus*, *Conops*, and *Musca*, after the removal of the *Syrphidæ*; but, owing to the numerous divisions and subdivisions necessary for its investigation, having but little to interest the general reader, we shall not here detail them.

Section II. (*Pupipara*); HOMALOPTERA, Leach.

Head immersed in the front of the thorax; sucker enclosed in two valves; claws with many teeth.

The transformation to the pupa state undergone in the body of the parent fly.

Fam. 1. (*Hippoboscidæ*). Head frontal.

Fam. 2. (*Nycteribidæ*). Head dorsal.

DIPTEROCARPEÆ—the camphor tree family.

A natural order of dicotyledonous plants, containing only a few genera and species. It is closely allied to *Elæocarpeæ*, but differs in its petals not being fringed, and in the want of albumen. It bears also an affinity to *Malvaceæ*, from which it is distinguished by its stamens being either distinct or only partially combined, by its long narrow two-celled anthers, and its pendulous ovules. To *Guttiferæ* it has also some affinity, but it is separated by its stipules and the contorted æstivation of its corolla. This order may be at once recognised by the enlarged leafy and unequal segments of the calyx while investing the fruit. Its essential characters are: calyx tubular, five-lobed, unequal, without bracteas, and imbricated; petals sessile, combined at the base with a twisted æstivation; stamens indefinite, distinct, or imperfectly polyadelphous; filaments dilated at the base; anthers awl-shaped, two-celled, opening longitudinally towards the apex; ovary superior, few-celled; ovules in pairs, pendulous; style and stigma simple; fruit coriaceous, one-celled, indehiscent or three-valved, surrounded by the enlarged foliaceous calyx; seed single, without albumen; cotyledons twisted and folded, or unequal and obliquely incumbent; radicle superior.

The plants of this order are large and elegant forest trees abounding in resinous juice. Their leaves are alternate, involute, with numerous parallel veins running from the midrib to the margin. They have deciduous oblong stigmas which terminate the branches in a taper point, and their flowers are generally large.

They are found only in the eastern islands of the Indian Archipelago.

This order, though small, is important on account

of the resinous juice which it furnishes. Its properties may be said to be stimulant and balsamic.

The chief genera of the order are, *Dipterocarpus*, *Dryobalanops*, *Shorea*, and *Vateria*.

*Dryobalanops Camphora* is interesting on account of yielding the camphor of Sumatra. In that island this tree is confined to the country of the Battas, which extends about one degree and a half to the north of the equator. It is also found in Borneo in nearly the same parallel of latitude. The camphor is found in a concrete crystallised state in fissures and cavities in the interior of the tree. It is less volatile than the common camphor of commerce, which is the product of *Laurus Camphora*, a native of Japan and China. On account of its scarcity it bears a very high price. It is little known in this country, or even in Europe. An oil is procured from the camphor tree by incision, which is supposed to be the first stage of the formation of camphor.

An account of camphor and its medical uses will be given under the article LAURINEÆ.

*Shorea robusta* affords a balsamic resin, which is used in the Indian temples.

By boiling the fruit of *Vateria Indica*, a tree common on the Malabar coast, a kind of tallow rises to the surface which concretes on cooling. It is whitish, greasy to the touch, and has rather a disagreeable odour. It is extremely tenacious and solid, but melts at the temperature of  $97\frac{1}{2}^{\circ}$  Fahrenheit. In the town of Mangalore it is sold for about twopence halfpenny a pound.

**DIRCA** (Linnæus). A small deciduous shrub, native of Virginia, in which country it is called leather-wood, perhaps from the toughness of the fibres of the inner bark. The flowers are inconspicuous, are octandrous, and the plant belongs to the natural order *Thymelææ*. It is usually planted among North American plants, and is propagated by layers.

**DISA** (Bergier). A genus of curious flowering plants, natives of the Cape of Good Hope. Linnæan class and order *Gynandria Monogynia*, and natural order *Orchideæ*. These plants thrive best planted in a pit with other Cape bulbs or tubers, in soil composed of loam, moor earth, and sand. They only need water when in a growing state.

**DISCINA** (Lamarck). This genus of molluscs has been so called from each valve presenting, near the centre, a remarkable and very distinct orbicular disk; that on the superior or upper side is smooth and pierced, exhibiting in its centre a small papillary elevated summit, giving it much the appearance of a patella: it is also surrounded by a margin longitudinally marked with delicately radiating striæ. The disk of the lower margin is very white, obliquely crossed by a notch or cleft, open on both sides. Although the valves of the shell are of an equal size, they are not exactly similar, the upper one being rather more convex, and the lower without striæ round its disk: there are no traces of hinge, ligament, or muscular impressions visible. It is found on the British coast affixed to stones. Sowerby observes this genus should be entirely expunged. Lamarck having constituted it from examples of the *Orbicula*, without mature consideration, it therefore must now form a subdivision of the genus *Orbiculina*.

**DISCOBOLUS**, so called from the ventral fins, forming a disk on the under part of the body, by means of which the fishes are enabled to hold on upon the points of rocks, and there catch their food, which

is brought to them by the currents. They form the third family of Cuvier's soft finned fishes, with the ventrals under the pectorals. They are fishes of small size, and altogether uninteresting for economical purposes. They are, however, curious on account of their form, and of the habit which we have mentioned. There are only two genera in the family, and the species are not numerous.

**LEPADOGASTER**—the Sucker. The members of this genus are very small fishes; their pectoral fins are very large, and reach the middle of the under part. They are composed of very strong rays, a little divergent in the front, and united by a membrane which is elastic, and which also includes the ventrals. Their bodies are smooth and without scales, the head depressed, and the muzzle projecting and capable of distension. Their gill openings are small, with four or five rays in the gill-flap. They have one soft dorsal fin immediately over the anal. Their intestinal canal is short, straight, and without those appendages, which would show that they are animal feeders. They have no air bladder, notwithstanding which they swim with considerable rapidity. There are several species found in the European seas, and on the British shores; but on the south and west rather than the east. The following are the British species.

**L. CORNUBIENSIS**—the Cornish Sucker, is about four inches in length, and reddish, with dusky spots. When full grown there are two eye-shaped marks behind the eyes, with a brownish marginal ring, a bright purple disk, and a small spot of intense blue in the centre. There are also four little fleshy filaments in front of the eyes, and the snout is produced, rounded and flattened. They are met with on the coast of Cornwall, and also in some parts of the Hebrides; and there is no doubt that if they were of any value to the fishermen they might be found upon all the rocky shores which are washed by the Atlantic, especially where a current of tide sweeps along. They are met with at low water adhering to the rocks, by means of their disk.

**L. BIMACULATUS**—Two-spotted Sucker. The length of this species is only about an inch and a half, and the body is more slender and the snout more pointed than in the former, and it is furnished with no appendages in connection with the eyes; the general colour is pink spotted with white; and when mature there is a spot of purple with a white margin behind each pectoral fin. This species is found in the Channel, and does not appear to be so decidedly a current fish as the other; but it adheres to stones and shells. These two species have the dorsal and anal fins distinct from the caudal; but there are several species which inhabit the Mediterranean which have these appendages united. There is nothing, however, in their history which can particularly interest the general reader.

**CYCLOPTERUS**—Circular Fin. The most remarkable structural character of this genus is that from which it is named. The ventral fins are united into one disk, which surrounds a considerable portion of the under side, forming a very efficient sucker, by which they can fix themselves firmly to rocks, to the bottoms of ships, or to the bodies of the larger fishes. Their mouths are large, and furnished with small pointed teeth in both jaws, and also in the pharynx. Their gill openings are small and closed below, with six rays in the flap. Their pectoral fins are very large, and they are continued and united under the throat,

in front of the disk formed by the pectorals. Their bones are soft, and their skin viscous and without scales; but it is sprinkled with minute grains of a hard substance. Their stomachs are very large, their intestines long and abundantly furnished with cæca, characters which indicate habits very different from the former genus, with which they have sometimes been confounded.

**DISPERIS** (Swartz). An orchideous genus from South Africa, which succeeds, if potted, or planted in a pit in compost made of a mixture of loam and peat earth.

**DISPORUM** (Salisbury). A genus of perennial herbs from China and Nepal. Class and order *Hexandria Monogymia*, and natural order *Melanthaceæ*. Generic character: corolla of six petals, bell-shaped, nectariferous holes at the base of the segments; stamens under the germen; filaments very short; style abbreviated; stigmas three-capsuled, three-valved; seeds membranous. According to Sweet, these plants are hardy enough to stand on a warm border, if sufficiently defended from frost.

**DIURIS** (Smith). A genus of curious plants from New Holland, belonging to the natural order *Orchidææ*. They are much easier cultivated than the South American species of the same order; only requiring to be potted in moor-earthly soil, and kept in a pit or green-house safe from frost.
